Abstract—A digitally-assisted leakage current supply (LCS) circuit reduces the maximum current demand for analog low-dropout (LDO) voltage regulators to lower the minimum dropout voltage ($V_{D\text{OMIN}}$), and consequently, enable a wider range of LDO operation for power savings in system-on-chip processor cores. From silicon measurements in a 130nm test chip, the LCS assisted hybrid LDO decreases $V_{D\text{OMIN}}$ by 30–38%, resulting in core power reduction of 21-28% at equal clock frequencies within the wider LDO operating range.

I. INTRODUCTION

Industrial system-on-chip (SoC) processors contain a number of distinct supply voltage ($V_{DD}$) rails driven from a power management integrated circuit (PMIC). A cluster of SoC processor cores share the same $V_{DD}$ and clock frequency ($F_{CLK}$) from a dedicated phase-locked loop (PLL). Each core in a cluster must either operate at the same $V_{DD}$ and $F_{CLK}$ as the other cores in the cluster or disable operation with a power gate configuration. With on-chip low-dropout (LDO) voltage regulators [1-8], each cluster on a shared voltage rail may employ a unique $V_{DD}$ and $F_{CLK}$. In this case, the cluster requiring the highest $V_{DD}$ and $F_{CLK}$ determines the shared $V_{DD}$ rail. A cluster with a lower target $V_{DD}$ and $F_{CLK}$ always operates at the lower $F_{CLK}$ for a linear $F_{CLK}$ power reduction. If this cluster satisfies the LDO minimum dropout voltage ($V_{D\text{OMIN}}$) requirement, this cluster executes at the lower target $V_{DD}$ via LDO mode for an additional linear $V_{DD}$ power reduction, which accounts for the LDO power loss. The dual-core design in Fig. 1 represents two separate clusters on a shared voltage rail ($V_{IN}$) with each cluster containing a unique core, $F_{CLK}$ generator, and power management unit (PMU).

Premium-tier SoC CPU cores typically prefer analog LDOs to satisfy the high-bandwidth requirements for fast transient performance. Area-constraints on the size of the power PFET (i.e., transistor $M_{PA}$ in the PMU in Fig. 1) typically limits the current drive in an analog LDO and results in higher $V_{D\text{OMIN}}$. The $V_{D\text{OMIN}}$ values of high-bandwidth analog LDOs range from 150-300mV in order to supply the core maximum current demand at the worst-case dynamic and leakage power conditions [3, 4]. A key challenge in industrial analog LDOs is this large $V_{D\text{OMIN}}$, which limits the opportunities to enable LDO mode for voltage scaling power benefits.

In recent years, all-digital LDOs have received significant attention to address the $V_{D\text{OMIN}}$ issue [1, 2, 6]. While digital LDOs have a lower $V_{D\text{OMIN}}$ requirement as the power PFETs operate in the linear region, these designs suffer from low gain and high output ripple due to limit cycle oscillations [1]. Hence, high-bandwidth analog LDOs are preferred in high-performance cores as compared to digital LDOs. Recently, hybrid LDOs [5, 7] employ both digital and analog loops to trade-off the strengths and weaknesses of traditional digital and analog designs. The challenge with the hybrid LDO designs is managing the complex current-load sharing between the analog and digital loops while maintaining high-bandwidth and stability. The load sharing problem often leads to an overdesign of both the analog and digital loops. This paper describes a digitally-assisted leakage current supply (LCS) circuit and 130nm test-chip measurements to reduce the maximum current demand for analog LDOs. The low-bandwidth LCS circuit supplies the slow-changing leakage current and the high-bandwidth analog LDO supplies the fast-changing dynamic current. By decreasing the maximum current requirement for the analog LDO, the LCS reduces the analog LDO $V_{D\text{OMIN}}$, resulting in core power savings.

II. TEST-CHIP DESIGN

The block diagram in Fig. 1 captures the behavior of an industrial SoC with two cores on a shared voltage rail with each core containing a separate $F_{CLK}$ generator and PMU to allow unique core voltage ($V_{CORE}$) and $F_{CLK}$ operation. The PMU in Fig. 1 consists of header switches (HS), analog LDO, and an LCS circuit to allow four configurations as described in Table 1. (1) Power gate mode with the analog LDO and HS disabled, (2) HS mode with the analog LDO disabled and HS enabled to

Directly connect VCORE to VIN, (3) LDO mode in the baseline design with LDO enabled and HS disabled, and (4) LDO mode in the proposed design with LDO enabled and the LCS circuit controlling the HS transistors. In the LDO mode for the proposed design, the LCS circuit supplies the slow-changing leakage current while the high-bandwidth analog LDO supplies the fast-changing dynamic current. By decreasing the maximum current requirement for the analog LDO, the LCS lowers the analog LDO V_D,MIN while keeping the power PFET (M_PA) in saturation, thus increasing the opportunities to enable LDO mode for core power reduction.

An alternative approach to reduce the headroom is to increase the width of the power PFET (M_PA). This leads to a larger PMU area and degrades the loop dynamics in both internal-pole and output-pole dominant analog LDO loops. As described in Table 2, if the analog LDO is output-pole dominant, then a wider M_PA shifts the internal pole at the gate of M_PA to a lower frequency, thereby reducing the phase margin. Conversely, if the analog LDO is internal-pole compensated, then a wider M_PA reduces the loop bandwidth, thus negatively affecting the response time to large load steps. To address these issues, the proposed LCS circuit enables a lower V_D,MIN while minimizing the impact on the area and the analog loop dynamics. In the proposed design, the LCS circuit supplies a portion of the load current. This is particularly effective at high temperatures when the leakage current, and hence, the total load current is the highest. Due to load sharing, the analog power PFET (M_PA) is smaller, thus decreasing the gate capacitance and allowing a higher frequency pole compared to a baseline analog-only design. As a result, the proposed design fully integrates an output-pole dominant, capacitor-less analog LDO with superior performance as summarized in Fig. 2.

From Fig. 1, load sharing through the HS devices is enabled by the LCS circuit. The LCS circuit includes: (1) Leakage-current-starved ring oscillator (RO), as described in Fig. 2, to monitor the changes in core leakage across temperature (T) and process variation, (2) RO frequency counter to map the RO frequency output (F_RO) to a digital signature over a programmable period of time (e.g., 1ms), and (3) Control logic that receives the digital signature to enable a target number of HS transistors to supply the load leakage current. The LCS leakage-current-starved RO contains an NFET footer device with a control voltage (V_CNTL) biased below the NFET threshold voltage (V_TH). From silicon measurements, a V_CNTL of 200mV ensures the voltage discharge of the internal RO nodes is governed by the NFET leakage current to allow the RO frequency (F_RO) to track leakage current while maintaining a sufficiently high F_RO to allow leakage monitoring and LCS configuration every 1ms. The control logic requires post-silicon characterization to determine the configuration register settings. An external on-board circuit

The test-chip contains a three-stage pipeline circuit in Fig. 3 with built-in self-test to mimic core functionality and scan programmable NFETs to generate realistic load steps.

The output-pole dominant analog LDO in Fig. 4 features a two-stage error amplifier design, consisting of an operational transconductance amplifier (OTA) stage with a low-output capacitance followed by a shunt feedback stage with a low-output resistance. This places the internal poles of the system at high frequencies (i.e., 100s of MHz), which is well beyond the unity gain bandwidth of the loop. The dominant pole of the analog amplifier is at the output node (V_{CORE}). Even with a small load capacitance of 400pF and no external capacitance, the worst-case phase margin is simulated at 88°. Excellent light load stability allows the analog LDO to provide retention voltage to the load circuits, when state preserving flip-flops consume ~100 A of total current.

III. MEASUREMENT RESULTS

Measured oscilloscope captures in Fig. 5 with V_{IN}=1.2V, T=85°C, and a dropout of 180mV demonstrate that the baseline design fails to regulate under a load step, whereas the LCS

Fig. 7: Measured LCS leakage-current-starved RO frequency (F_{RO}) versus core leakage current (I_{LEAK}) with temperature ranging from 25°C to 85°C for each die.

Fig. 8: Measured voltage drop (V_{DROOP}) and effective V_{CORE} versus V_{REF} for a load step from 0.8mA to 2.8mA. (Dotted Lines: Analog LDO, Solid Lines: LCS assisted hybrid LDO) assisted hybrid LDO continues to regulate. In comparison to the analog LDO, measurements in Fig. 6 reveal that the LCS assisted hybrid LDO reduces V_{DO,MIN} by 30-38% for three different V_{IN} values. The efficacy of the LCS assisted hybrid LDO is most pronounced at high T (85°C), where leakage is high, providing an additional 9-14% V_{DO,MIN} reduction relative to the analog LDO as compared to T=25°C.

From measurements in Fig. 7 across four dies and T ranging from 25-85°C, the leakage sensor F_{RO} closely tracks the changes in core leakage current. For an industrial SoC processor, this data indicates that post-silicon characterization of a relatively small number of parts (e.g., 100s) across wide ranges of T can provide the configuration register settings for the LCS control logic for every part in high-volume shipping, thereby avoiding the expensive test time of per part calibration. Detailed transient measurements in Fig. 8 of the proposed design as compared to the analog LDO at V_{IN}=1.2V and T=85°C with a load step from 800µA to 2.8mA demonstrate:

(a) Voltage drop (V_{DROOP}) becomes worse in both designs as the reference voltage (V_{REF}) increases due to the diminishing

loop gain, (2) Analog LDO regulates until 0.94V, whereas the LCS assisted hybrid LDO operates until 1.02V, thus providing an extended operating range, and (3) Effective core voltage \( (V_{REF}-V_{DROOP}) \) is 46mV higher in the proposed design at an extended operating range, and (2) Analog LDO regulates until 0.94V, whereas the LCS assisted hybrid LDO operates until 1.02V, thus providing lower \( V_{D_{MIN}} \) as compared to traditional analog LDO solutions. Fig. 13 describes the chip micrograph and characteristics.

### IV. CONCLUSIONS

A digitally-assisted leakage current supply (LCS) circuit lowers the maximum current requirement for analog LDOs to reduce the minimum dropout voltage \( V_{D_{MIN}} \), thus expanding the LDO operating range for reducing SoC core power. Silicon measurements from a 130nm test chip demonstrate that the LCS assisted hybrid LDO lowers \( V_{D_{MIN}} \) by 30-38%, resulting in core power reduction of 21-28% at iso-FCLK within the wider LDO operating range.
