

Leverage Dynamics without Commitment

PETER M. DEMARZO AND ZHIGUO HE*

forthcoming in the *Journal of Finance*

June 2020

ABSTRACT

We characterize equilibrium leverage dynamics in a tradeoff model when the firm can continuously adjust leverage and cannot commit to a policy *ex ante*. While the leverage ratchet effect leads shareholders to issue debt gradually over time, asset growth and debt maturity cause leverage to mean revert slowly towards a target. Investors anticipate future debt issuance and raise credit spreads, fully offsetting the tax benefits from new debt. Shareholders are consequently indifferent toward the debt maturity structure, even though their choice may have a significant effect on credit spreads, leverage levels, the speed of adjustment, future investment and growth.

Understanding the determinants of a firm’s capital structure and how its leverage is likely to evolve over time is one of the central questions in corporate finance. Leverage and its expected dynamics are crucial to valuing the firm, assessing its credit risk, and pricing its financial claims. Forecasting the optimal response of leverage to shocks, such as the 2007–2008 financial crisis, is necessary to anticipate the likely consequences of a crisis and its aftermath, and to evaluate alternative policy responses.

Despite its importance, a fully satisfactory theory of leverage dynamics has yet to be found. Many models assume the absolute level of debt is fixed; for example, in the traditional framework of Merton (1974), as well as Leland (1994, 1998), the firm is committed not to change its outstanding debt before maturity, irrespective of the evolution of the firm’s fundamentals. As a result, the dynamics of firm leverage is driven solely by the stochastic growth in value of the firm’s assets-in-place. More recent work that allows the firm to restructure its debt over time typically assumes that all existing debt must be retired (at a cost) before any new debt can be put in place.¹ These assumptions are neither innocuous, as the constraints on leverage generally bind in the model, nor are they consistent with practice, where firms often borrow incrementally over time. See, for example, Figure 1, which shows how debt levels for American and United Airlines changed over time in response to fluctuations in their enterprise values (market value of equity plus book value of debt).

In this paper, we study a model in which equity holders lack the ability to commit to their future leverage choices and can issue or buy back debt at the prevailing market price at any time. Aside from corporate taxes and default costs, there are no other frictions or transactions costs in our model. Because debt can be freely adjusted over time, the firm *could* increase debt to exploit tax shields when cash flows are high and also reduce debt to avoid distress costs when cash flows fall, thereby avoiding the standard leverage “tradeoff.” But although such an ideal policy is *feasible*, it is not time consistent. As emphasized by Admati et al. (2018), the desire of equity holders to maximize the current share price leads to a “leverage ratchet effect” in which equity holders are never willing to voluntarily reduce leverage, but always have an incentive to borrow more—even if current leverage is excessive and even if new debt must be junior to existing claims.

¹ See e.g., Fischer, Heinkel, Zechner (1989), Titman and Tsyplakov (2007), Goldstein, Ju, and Leland (2001), Strebulaev (2007), and Dangl and Zechner (2016).

Figure 1. Time-series of outstanding book debt and enterprise value for American and United Airlines, for fifteen years before their bankruptcies in 2011 and 2002, respectively. Book debt is calculated as the sum of “long-term debt” and “debt in current liabilities,” and market equity is calculated as the product of “stock price” and “common shares outstanding.” Data source: WRDS.

In this paper we solve for the equilibrium leverage dynamics that emerge when the firm cannot commit to a future leverage policy. We show that as a result of the leverage ratchet effect: (i) the firm issues debt smoothly, and leverage adjust slowly to changes in firm profitability; (ii) although shareholders never repurchase debt, leverage mean-reverts to a target due to asset growth and debt maturity; (iii) even though the interest tax shield motivates debt issuance, in equilibrium credit spreads rise to the point that the firm is unable to capture these tax shields; (iv) default costs and investment distortions fully offset the benefits of leverage, so that the firm is indifferent to its future debt maturity structure.

Solving dynamic leverage models is complicated by the interdependence between current debt prices and the firm’s future leverage and default decisions. We develop a methodology to characterize the no-commitment equilibrium in a general setting that allows for finite maturity debt, asset growth, investment, and both Brownian and Poisson shocks. In equilibrium, equity holders issue debt gradually over time, at a rate which depends on the current profitability of the firm. Equity holders find it optimal to issue new debt to exploit tax benefits even after the firm’s leverage passes above the “optimal” level with commitment, leading to excessive inefficient

default.² Firms never actively reduce leverage, but do allow it to decline passively via debt maturity or asset growth. Creditors anticipate the devaluation associated with future over-borrowing and consequently lower the price they are willing to pay for the debt today. Higher credit spreads offset the tax advantage of leverage, which slows the rate of issuance to the point that, on the margin, equity holders are indifferent to leverage increases. We show that this effect is so strong that equity holders obtain the same value in equilibrium *as if* they committed not to issue any debt in the future. In other words, the extra tax shield benefits that tempt shareholders are exactly dissipated by the bankruptcy costs caused by excessive leverage.

The result that all gains from trade are dissipated in equilibrium is closely related to the Coase's (1972) conjecture regarding durable goods monopoly. In this context, the firm is a monopoly supplier of its own debt, and creditors' valuation of the debt depends on the total quantity supplied. In our model, as Coase conjectured, the equilibrium debt price falls to the marginal (after-tax) cost to shareholders, and shareholders are thus unable to capture the gains from trade.³

We apply our methodology to the special case of geometric Brownian motion (as in Leland 1994) and solve in closed form for the debt price and issuance policy in the unique Markov perfect equilibrium (MPE). Debt accumulates over time at a rate that increases with profitability, but if profits decline sufficiently, new issuance drops below the rate of debt maturity and hence the debt level falls. Leverage is thus path dependent, and the firm's outstanding debt at any point of time can be explicitly expressed in terms of a weighted-average of the firm's past earnings. The firm's interest coverage ratio mean reverts gradually, with the speed of adjustment decreasing with debt maturity and asset volatility. Our model thus provides a theoretical foundation for partial adjustment models (e.g., Jalilvand and Harris 1984; Leary and Roberts 2005; and more recently, Frank and Shen 2019) that are widely used in the empirical capital structure literature. Importantly, these dynamics differ from the abrupt adjustment to a "target" leverage level implied by models

² This result holds even when there is *no* dilution motive to issue debt (either because there is zero recovery value in bankruptcy, or debt is prioritized so that newly issued debt must be junior to all existing debt). However, even without a direct dilution effect, there is an indirect "dilution" or devaluation effect associated with new debt issuance, as additional leverage raises the probability of default for all debt holders.

³ Though note that, unlike in Coase's setting, marginal cost (which is the equilibrium debt price) is endogenous in our model, and investors share a common valuation for the asset. Similar results can be found in DeMarzo and Urošević (2006) in the context of trading by a large shareholder, and Daley and Green (2018) in which a monopolistic buyer makes frequent offers to a privately informed seller.

with an exogenous adjustment cost (for instance, Fischer, Heinkel, Zechner 1989; Goldstein, Ju, Leland 2001; and Strebulaev 2007).

We compare our model without commitment to the benchmark in which shareholders commit to *never* issue debt in the future. We show that equity prices coincide in both settings, whereas bond investors' anticipation of future borrowing causes credit spreads to be much larger in the setting without commitment. For a firm that is initially unlevered, we show that this high cost of debt might dissuade it from borrowing altogether, and thus help explain the zero-leverage puzzle (Strebulaev and Yang 2013).

We also study the optimal debt maturity structure. Our model without commitment provides a fresh perspective on this question. We show that at every point in time, shareholders are indifferent to the maturity choice for future debt issuance. Short maturity debt leads to higher leverage on average, as shareholders issue debt more aggressively knowing leverage can be reversed more quickly when the short-term debt matures. Nevertheless, the gain from additional tax shields is offset by increased default costs. Thus, the agency costs associated with the leverage ratchet effect are bounded away from zero even as debt maturity becomes arbitrarily short.

Although firms are indifferent to the debt maturity choice, alternative maturity structures produce very different leverage dynamics. Thus, small perturbations or frictions that lead firms to select a particular initial maturity structure can lead over time to dramatically different leverage outcomes.⁴ In addition, because leverage mean reverts slowly, even firms with the same debt maturity may have persistent differences in leverage resulting from past shocks. These results provide a potential explanation for findings such as those by Lemmon, Roberts, and Zender (2008) that much of the cross-sectional variation in firms' capital structure is persistent and largely unexplained by observable firm characteristics.

Finally, we consider the interaction of the firm's leverage and investment policies. When the firm cannot commit to its investment policy, leverage distorts investment due to debt overhang.

⁴ The choice of debt maturity structure does affect the value of equity if the firm is forced to borrow a fixed amount up front. Indeed, this question has been studied in the Leland (1998) setting, and often long-term debt, which minimizes rollover risk, is preferred (He and Xiong 2012; Diamond and He 2014). In contrast, we show that without commitment firms prefer short-term debt for any positive targeted debt financing. Short-term debt has lower price impact because it allows the firm to quickly reduce leverage through maturity. (Another possible force favoring short-term debt is investors' liquidity preference, which is modeled in He and Milbradt (2014).) On the other hand, if the firm is not forced to issue debt initially, we show that long-term debt is preferred from a social perspective because the firm will accumulate its debt more slowly, reducing the expected deadweight losses from default.

The firm tends to issue new debt more slowly, and targets a lower level of leverage in the presence of debt overhang. Near default, however, shareholders raise current cash flows by cutting investment inefficiently and issuing debt more aggressively than if investment were fixed. In equilibrium, under-investment costs substitute for default costs, again to the point that expected future tax benefits are exactly offset. As a result, the ability to commit to an investment policy does not improve the ex ante value of the firm, in contrast to standard tradeoff models.⁵ Furthermore, tax policies or other subsidies designed to promote investment by lowering the cost of debt may instead reduce investment in equilibrium (see also Crouzet and Tourre (2020)).

Our paper is most closely related to Admati et al. (2018). They demonstrate the leverage ratchet effect in the context of a one-time leverage adjustment and then numerically evaluate a dynamic equilibrium in a stationary model with regime shocks and perpetual debt. Our paper studies leverage dynamics in a richer continuous-time framework that allows for both asset growth and debt maturity, as well as both Brownian and Poisson shocks. As one of the main contributions of the paper, we develop a general methodology to solve for an important class of equilibria. For the standard workhorse model of Leland (1994), we not only solve for the equilibrium in closed form that allows for deeper analysis, but also establish the uniqueness of this equilibrium.

In Dangl and Zechner (2016), the firm can choose how much maturing debt to roll over, but covenants prevent the firm from increasing the total face value of debt outstanding without first repurchasing all existing debt (at par plus a call premium and a proportional transaction cost). Rolling over debt not only maintains the firm's tax shields, as in our model, but also directly dilutes current creditors given their setting with a strictly positive recovery rate and pari passu debt (which we analyze in Section II.D). They show that when debt maturity is long, equity holders will roll over existing debt fully as it comes due, except for when leverage is so low that recapitalization to a higher face value of debt is imminent (in which case it is not worthwhile to issue debt that is likely to be replaced soon, at a cost). If debt maturity is sufficiently short, however, then when facing high leverage, shareholders may roll over only a portion of the maturing debt so that the total face value of debt gradually declines. This behavior abruptly reverses when the firm approaches default as shareholders maximize dilution (and minimize equity injections) by again

⁵ In other words, solving the commitment problem regarding the firm's leverage policy is *necessary* for the firm to benefit from being able to commit to an investment policy.

rolling over debt fully.⁶ Importantly, they show that firm value is not monotonic in debt maturity; depending on the parameters, an interior optimal maturity may exist that trades off the transactions costs of debt rollover (which favors long maturities) with the benefit from debt reductions given high leverage (which favors short maturities).⁷ As in our model, the choice of debt maturity becomes an important commitment device that allows for future debt reductions in the face of negative shocks.

Benzoni et al. (2020) study the role of commitment when the firm faces a *fixed* transaction cost when issuing new debt. They consider the class of “*s-S*” capital restructuring policies as in Goldstein, Ju, and Leland (2001) and compare outcomes when the firm can commit to the restructuring boundary to those when it cannot. Naturally, commitment leads to a strictly higher equity value. They also argue that when fixed costs are small and the debt maturity is sufficiently short, equity values without commitment to the restructuring boundaries are close to the outcome with commitment.

In the literature of endogenous debt dynamics in the presence of real investment opportunities, Hennessy and Whited (2005) study one-period short-term debt and highlight the importance of a dynamic framework in testing tradeoff theories empirically. Abel (2016) considers a continuous-time model with investment in which firms adjust leverage by issuing debt with instantaneous maturity. Abel assumes i.i.d. regime shocks to profitability and shows that in response to a shock, shareholders never reduce the amount of debt and only firms that are borrowing constrained (i.e., firms that have borrowed an amount equal to 100% of firm value) choose to increase debt.

Our results in this paper highlight the fact that some form of commitment is necessary to capture the potential gains from leverage. DeMarzo (2019) extends our model to incorporate collateral and related commitment mechanisms. Collateral is valuable because it resolves the non-exclusivity problem underlying the leverage ratchet effect, making the value of secured debt insensitive to total leverage. Collateral lowers the cost of capital, and the optimal leverage jumps

⁶ In the extension of our model in which we allow for direct dilution, because there is no constraint on the rate of issuance, we show that the debt issuance rate increases only at the moment of default.

⁷ The same tradeoff would apply in our model if we were to adopt the same assumption on transaction costs. A similar tradeoff exists in Brunnermeier and Yogo (2009), who stress the advantage of short-term debt in providing the firm with flexibility to adjust debt quickly in the face of shocks to firm value, while long-term debt is more effective at reducing costs from rollover risk.

discretely whenever new collateralizable assets are acquired. The model thus reconciles the empirical evidence regarding the persistence and slow adjustment of capital structure with the strong predictive power of collateral. DeMarzo (2019) also discusses the role and importance of other forms of commitment mechanisms, and the resulting ex-post rigidity of capital structure, to enhance firm value.

Our paper proceeds as follows. In Section I we introduce a general continuous-time model of the firm and develop our methodology for solving for an equilibrium in which shareholders adjust debt continuously. Section II applies our general results to the special case when cash flows are lognormal with possible jumps and derives a closed-form solution for security prices and debt issuance. We also consider the case of positive recovery and alternative default regimes with pari passu debt. Section III analyzes debt dynamics and shows that the firm gradually adjusts leverage towards a target level. We then evaluate the firm's choice of debt maturity and on the share price and social welfare, and also relate our results to empirical puzzles regarding low leverage firms. Section IV extends the model to include agency costs of investment, and Section V concludes.

I. A General Model

We consider a firm whose cash flows follow a general jump-diffusion process that encompasses typical settings used in the literature, and include both corporate taxes and bankruptcy costs as in a standard tradeoff model. We depart from the existing literature by assuming that the firm cannot commit to its future capital structure choices, but instead is free to issue or repurchase debt at any time to maximize the current share value. We analyze the equilibrium no-commitment leverage policy in this setting.

In general, the optimal leverage policy depends on equilibrium debt prices, but debt prices depend on the firm's anticipated *future* leverage choices, which determine the likelihood of default. Although this interdependence complicates the determination of an equilibrium, we show conditions for which we can construct and characterize the equilibrium leverage policy directly, and demonstrate that the rate of debt issuance is determined by the ratio of the tax benefits from new debt to its price sensitivity to new issues. Surprisingly, despite the issuance of new debt to exploit available tax shields, we show that shareholders do not benefit from this activity: the equilibrium share price is the same as if the firm committed not to issue any new debt in the future.

A. *The Firm and Its Securities*

All agents are risk neutral with an exogenous discount rate of $r > 0$.⁸ The firm's assets-in-place generate operating cash flow (EBIT) at the rate of Y_t , which evolves according to

$$dY_t = \mu(Y_t)dt + \sigma(Y_t)dZ_t + \zeta(Y_{t-})dN_t, \quad (1)$$

where the drift $\mu(Y_t)$ and the volatility $\sigma(Y_t)$ are general functions that satisfy standard regularity conditions; dZ_t is the increment of a standard Brownian motion; dN_t is an independent Poisson increment with intensity $\lambda(Y_t) > 0$; and $\zeta(Y_{t-})$ is the jump size given the Poisson event.⁹

Denote by F_t the aggregate face value of outstanding debt. The debt has a constant coupon rate of $c > 0$, so that over $[t, t + dt]$ debt holders receive coupon payments of $cF_t dt$.¹⁰ The firm pays corporate taxes equal to $\pi(Y_t - cF_t)dt$, where $\pi(\cdot)$ is a strictly increasing function of the firm's profit net of interest.¹¹ Hence the net after-tax cost to the firm of the marginal coupon payment is only $1 - \pi' < 1$ (with "prime" indicating derivative), reflecting the debt tax shield subsidy.

For simplicity, we assume that debt takes the form of exponentially maturing coupon bonds with a constant amortization rate $\xi > 0$. More specifically, at each instant, there are $\xi F_t dt$ units of required principal repayments from maturing bonds, corresponding to an average bond maturity of $1/\xi$. Debt retirement in this fashion is similar to a sinking fund that continuously buys back debt at par. Thus, combining interest and principal, equity holders are required to pay debt holders a total flow payment of $(c + \xi)F_t dt$ in order to avoid default.

⁸ Alternatively, we can interpret the model as written under a fixed risk-neutral measure that is independent of the firm's capital structure decision.

⁹ We have simplified the notation by assuming the jump size $\zeta(Y_t)$ conditional on cash flow Y_t is deterministic. We can easily generalize the model to allow a random jump size $\tilde{\zeta}(Y_t)$, as long as the law of $\tilde{\zeta}(Y_t)$ depends on Y_t only.

¹⁰ The coupon rate c is exogenously given in our model, so newly issued debt might not be issued at par. In practice, there may be limits/adjustments to the tax deductibility of the coupon if it is far from the par coupon rate. For simplicity, we ignore the tax consequences of non-par debt issuance for this paper.

¹¹ Throughout, we use the terms "increasing" and "decreasing" in the weak sense, and add "strictly" as appropriate.

In the main analysis, we assume investors recover zero value from the assets-in-place when equity holders default. The key implication of this assumption, which will simplify our analysis, is that *debt seniority becomes irrelevant*. Because there are no claims to divide in default, old debt holders are *not* directly diluted by new debt holders, where “direct dilution” refers to a decrease in the share of any bankruptcy proceeds going to prior creditors.

We make the zero recovery value assumption to emphasize that our results are not driven by the direct dilution that arises when issuing pari passu debt (see, for example, Brunnermeier and Oehmke 2014 and Dangl and Zechner 2016). Instead, there is an “indirect dilution” effect in our model because the value of existing debt is adversely affected by the increased likelihood of default once new debt is issued. This indirect dilution effect is a form of debt overhang: shareholders exercise their default option earlier if the firm is more indebted. This effect arises even if debt is fully prioritized, with new debt always strictly junior to existing debt.¹² Nevertheless, in Section II.D we will consider the case with a positive recovery value in which the firm can issue new pari passu debt.

Equity holders control the outstanding debt F_t through an endogenous issuance/repurchase policy $d\Gamma_t$, where Γ_t represents the cumulative debt issuance over time (which is a right-continuous-left-limit process and measurable with respect to the filtration generated by $\{Y_s : 0 \leq s \leq t\}$).¹³ Given our debt maturity assumption, the evolution of the outstanding face value of debt F_t is given by

$$dF_t = d\Gamma_t - \xi F_t dt . \quad (2)$$

¹² Indeed, our qualitative results still hold with a positive recovery rate when new debt must be junior to existing claims. Extending the model in this way adds significant complexity, however, as debt securities issued at different times have distinct prices. In contrast, given zero recovery or pari passu debt, all debt is identical independent of the timing of issuance.

¹³ To rule out Ponzi schemes in which the firm avoids default by perpetually rolling over all debt, we must impose some upper bound $F_t \leq \bar{F}(Y_t)$ on debt, where the bound $\bar{F}(Y_t)$ exceeds the pre-tax unlevered value of the firm. This constraint will not bind in equilibrium and plays no role in the analysis.

Thus, the face value of debt will grow if the rate of issuance more than offsets the contractual retirement rate. To highlight the economic forces at play and in contrast to much of the literature, we assume zero transaction costs in issuing or repurchasing debt.¹⁴

Given the equity holders' expected issuance/repurchase policy, debt holders price the newly issued or repurchased debt in a competitive market. Denote by p_t the endogenous debt price per unit of promised face value. The debt price p_t reflect the information available up to date t , including the current debt issuance $d\Gamma_t$, and hence incorporates the price impact of new borrowing. Importantly, in equilibrium, p_t also reflects creditors' expectations regarding future leverage decisions. Then over the time interval dt , the net cash flows to equity holders are

$$\left(\underbrace{Y_t}_{\text{operating cash flow}} - \underbrace{\pi(Y_t - cF_t)}_{\text{tax payment}} - \underbrace{(c + \xi)F_t}_{\text{debt interest \& principal}} \right) dt + \underbrace{p_t d\Gamma_t}_{\text{debt issuance/repurchase}}. \quad (3)$$

The firm continues to operate until the operating cash flow Y_t drops low enough, relative to the outstanding debt level F_t , that equity holders find it optimal to default on their contractual obligation to debtholders. As in Leland (1994, 1998), shareholders cannot commit to a certain default policy, but instead default strategically. Again, for now we assume all investors receive zero cash flows post-default and consider alternative default payoffs in Section II.D.

B. Smooth Equilibrium

We focus on Markov perfect equilibria (MPE) in which the two payoff-relevant state variables are the firm's *exogenous* operating cash flow, Y_t , and the outstanding aggregate debt face value, F_t , which is an *endogenous* state variable. We will analyze the value function $V(Y_t, F_t)$ for equity and the debt price $p(Y_t, F_t)$. Denote by τ_b the equilibrium default time; that is, the first time that the state (Y_t, F_t) falls into the endogenous default region. We assume, for now, that all investors receive a payoff of zero if the firm defaults.

¹⁴ It is common in the dynamic capital structure literature, such as Fischer, Heinkel, and Zechner (1989) and Leland, Goldstein, and Ju (2000), to assume that firms must buy back *all* of their existing debt in order to issue new debt, and that there is a positive adjustment cost associated with this transaction. This behavior does not correspond to general practice, and we eliminate this constraint to highlight equity holders' intrinsic incentives to adjust leverage.

We begin by analyzing some general properties that must hold for any equilibrium. In particular, we show that shareholders never choose to repurchase debt, even if leverage is excessive from the perspective of total firm value. This result is a consequence of the leverage ratchet effect (Admati et al. 2018). In addition, the debt price is decreasing in the amount of debt outstanding, so that debt issuance negatively impacts the debt price.

PROPOSITION I (LEVERAGE RATCHET AND PRICE IMPACT). *In any MPE in (Y, F) , the firm never repurchases debt, and thus the issuance policy Γ_t is a monotonically increasing process. The equity value function $V(Y, F)$ is convex and decreasing in F , with the debt price as a subgradient:*

$$p(Y, F) \in -\partial_F V(Y, F).$$

Hence, the debt price is decreasing in F .

Proof: To see the convexity of $V(Y, F)$ in F , note that given any debt level F' , equity holders have the option to adjust debt to F by issuing $F - F'$ (buying back if this quantity is negative) at the price of $p(Y, F)$. Therefore, the value of the firm given F' must be at least as high as the value that equity would obtain by changing the debt level to F :

$$V(Y, F') \geq V(Y, F) + p(Y, F)(F - F') = V(Y, F) - p(Y, F)(F' - F), \quad (4)$$

establishing that the (negative) debt price is a subgradient of V . As a result, V is convex in F and debt price is decreasing in F . Because $p \geq 0$, V is also decreasing in F .

To see why shareholders would not benefit from a debt buyback, consider postponing a planned buyback by dt . Shareholders would save cost of the buyback (the debt price) today, but then continue to pay the *after*-tax coupons and principal until they repurchase the debt at time $t + dt$. Because the debt price today is equal to the present value of the *pre*-tax coupons, principal payments, and future debt price, shareholders profit from the delay by the amount of the tax shield. In addition, if they delay repurchasing the debt, they also maintain the option to default rather than repurchase. See the [appendix](#) for a formal proof. ■

Note that the negative impact of debt issuance on the debt price (i.e., the debt is traded at $p(Y, F)$ with F being the post-trade debt obligation) will deter shareholders from issuing a large

amount of debt at once. Indeed, if the value function is strictly convex (hence the debt price is strictly decreasing) in F , it would be optimal for the firm to adjust debt in a continuous manner.

LEMMA (CONTINUOUS ADJUSTMENT). *If the equity value function $V(Y, F)$ is strictly convex in F , then the debt price is strictly decreasing in F and the optimal issuance policy Γ_t is continuous in t .*

Proof: With strict concavity, the inequality in (4) becomes strict. Hence, any discrete issuance with $|F - F'| > 0$ would be suboptimal for shareholders. ■

This result motivates us to consider a special class of equilibria in which equity holders find it optimal to adjust the firm's outstanding debt smoothly, with $d\Gamma_t = G_t dt$, where G_t specifies the rate of issuance. From now on, we call this equilibrium a "smooth" equilibrium, and call G_t the equity holders' issuance policy (which must be nonnegative by **PROPOSITION I**).¹⁵

DEFINITION (SMOOTH EQUILIBRIUM). *A smooth equilibrium is a Markov perfect equilibrium in which the issuance policy is given by $d\Gamma_t = G_t dt$ for some adapted process G_t .*

In the remainder of this section, we develop a methodology to construct and characterize smooth equilibria. Later, in Section II, we consider a specific setting and rule out the existence of non-smooth equilibria.

C. Security Valuation

In a smooth equilibrium, given the debt price $p(Y, F)$, the firm's issuance policy G and default time τ_b , maximize the market value of equity:

$$V(Y, F) = \max_{\tau_b, G} E_t \left[\int_t^{\tau_b} e^{-r(s-t)} \left[Y_s - \pi(Y_s - cF_s) - (c + \xi)F_s + G_s p_s \right] ds \mid Y_t = Y, F_t = F \right]. \quad (5)$$

Because debt holders receive both coupon and principal payments until the firm defaults, and the firm recovery upon default is assumed to be zero, the equilibrium market price of debt must satisfy

¹⁵ Technically, there is also the possibility that the issuance policy might include a singular component, so that the sample path of Γ is continuous, but not absolutely continuous. We rule out such policies in our uniqueness proof in Section II.

$$p(Y, F) = E_t \left[\int_t^{\tau_b} e^{-(r+\xi)(s-t)} (c + \xi) dt \mid Y_t = Y, F_t = F \right], \quad (6)$$

where the expectation in (6) is under the evolution of F implied by G .

C.1 An Optimality Condition

Recall that we are interested in an equilibrium when there is no commitment by equity holders to future leverage policies. Thus, at any point in time, the issuance policy G_s for $s > t$ has to be optimal in solving the equity holders' instantaneous maximization problem at time s , given equity's value function and equilibrium debt prices.

In this section we consider the necessary and sufficient conditions for the optimality of the debt issuance policy G_t . The Hamilton-Jacobi-Bellman (HJB) equation for equity holders is

$$\underbrace{rV(Y, F)}_{\text{required return}} = \max_G \left[\underbrace{Y - \pi(Y - cF)}_{\text{after-tax cash flow}} - \underbrace{(c + \xi)F}_{\text{coupon \& principal payment}} + \underbrace{Gp(Y, F)}_{\text{new debt issuance}} + \underbrace{(G - \xi F)V_F(Y, F)}_{\text{evolution of } dF} \right] \quad (7)$$

$$+ \underbrace{\mu(Y)V_Y(Y, F) + \frac{1}{2}\sigma(Y)^2V_{YY}(Y, F) + \lambda(Y)[V(Y + \zeta(Y)) - V(Y)]}_{\text{evolution of } dY}.$$

In the first line, the objective is linear in G with a coefficient of $p(Y, F) + V_F(Y, F)$, which represents the (endogenous) marginal benefit of the revenue from a debt sale net of the marginal cost of the future debt burden on shareholders. If shareholders find it optimal to adjust debt smoothly, then it must be that this coefficient equals zero, or equivalently,¹⁶

$$p(Y, F) = -V_F(Y, F). \quad (8)$$

C.2 No Trade Valuation

The first-order condition (8) is a necessary condition for a smooth equilibrium. While straightforward, it has deep implications for the equilibrium value of equity in any smooth

¹⁶ While (7) implies (8) in the non-default region, it is also true in default, as for a defaulted firm the debt price $p = 0$ and $V(Y, F) = V_F(Y, F) = 0$. (We extend the model to the case with positive recovery in Section II.D.) Also, the debt price for $F = 0$ is relevant only if the firm were to buy back all of its debt (which is off-equilibrium according to **PROPOSITION I**), and hence setting $p(Y, 0) \geq -V_F(Y, 0)$ is sufficient for optimality.

equilibrium. Plugging condition (8) into the equity HJB equation (7), we have the following revised HJB equation for equity:

$$rV(Y, F) = Y - \pi(Y - cF) - (c + \xi)F + \mu(Y)V_Y(Y, F) - \xi F V_F(Y, F) + \frac{1}{2}\sigma(Y)^2 V_{YY}(Y, F) + \lambda(Y)[V(Y + \zeta(Y), F) - V(Y, F)]. \quad (9)$$

This equation says that in the no-commitment equilibrium, the equity value can be solved *as if* there is no debt adjustment $G \equiv 0$ (except for the natural retirement at rate ξ).

Note that when $G \equiv 0$, the value of equity is independent of the debt price, and thus is the solution to a standard optimal stopping problem in which Y_t follows (1) and $dF_t = -\xi F_t dt$. These problems are well studied in the literature, as are conditions ensuring the uniqueness and smoothness of the solution.¹⁷ We denote the corresponding no trade equity value function by $V^0(Y, F)$; here, “no trade” simply means shareholders do not participate in the debt market. In other words, V^0 satisfies (9) and is the solution to (5) when G is constrained to be zero. The preceding argument then implies that the equity value must equal this no trade value in any smooth equilibrium:

PROPOSITION II (NO TRADE EQUITY VALUATION). *In any smooth equilibrium, the value of equity is equal to the no trade valuation: $V(Y, F) = V^0(Y, F)$.*

Proof: Because equity holders can always choose not to trade, $V(Y, F) \geq V^0(Y, F)$ for any equilibrium. Next, given any smooth equilibrium with value function V , (7) and (8) imply (9), and as a result setting the issuance policy to $G = 0$ does not change the equity value V . Hence, the value V under this equilibrium could be obtained with no trade. But because V^0 is the optimal value with no trade (with a potentially superior default policy), $V(Y, F) \leq V^0(Y, F)$. Combining both, we have $V(Y, F) = V^0(Y, F)$. ■

Intuitively, because equity holders gain no marginal surplus from adjusting the debt level, their equilibrium payoff must be the same as if they were to never issue/repurchase any debt. This result, while perhaps striking at first, is analogous to the Coase (1972) conjecture for durable goods

¹⁷ See, for example, chapter 10 of Oksendal (2013), which analyzes a case with a finite-dimensional diffusion. Recently, Ishikawa (2011) offers an analysis covering the case of jump-diffusion processes. We assume that the appropriate technical conditions hold throughout the paper.

monopoly—the firm is a monopolist issuer of its own debt. When a monopolist is unable to commit to restricting its future sales, it cannot resist the temptation to sell aggressively, so much so that the endogenous price falls to marginal cost and any surplus from trading gets dissipated in equilibrium.¹⁸

C.3 Optimal Debt Issuance

PROPOSITION II implies that if a smooth equilibrium exists, we may compute the equity value function *as if* there were no further trade and the firm gradually retires its existing debt. Given the equity value V , we can then invoke the first-order condition in (8) to obtain the equilibrium debt price $p(Y, F) = -V_F(Y, F)$.

The question remains, however, whether this debt price is consistent with a smooth issuance policy G that is also optimal for shareholders. It is straightforward to show that $G = 0$ cannot be an equilibrium, as in that case the debt price would exceed its marginal cost to shareholders due to the interest tax shield, and so shareholders would find $G > 0$ optimal.¹⁹ But as the rate of issuance increases, the likelihood of default will increase and the price of debt will fall to the point that (8) holds.

To determine the equilibrium debt issuance policy, which we denote by G^* , we see from (6) the debt price must satisfy the standard HJB equation,

$$\underbrace{rp(Y, F)}_{\text{required return}} = \underbrace{\underline{c}}_{\text{coupon}} + \underbrace{\xi(1-p(Y, F))}_{\text{debt retirement}} + \underbrace{(G^* - \xi F)p_F(Y, F)}_{\text{evolution of debt } dF} + \underbrace{\mu(Y)p_Y(Y, F) + \frac{1}{2}\sigma(Y)^2 p_{YY}(Y, F) + \lambda(Y)[p(Y + \zeta(Y), F) - p(Y, F)]}_{\text{evolution of cash flow } dY}. \quad (10)$$

Next, starting with the HJB equation (9) for $V(Y, F)$, if we differentiate by F and use the optimality condition $p = -V_F$, we obtain

¹⁸ A closely related result appears in DeMarzo and Urošević (2006) in a model of trade by a large shareholder trading off diversification benefits and price impact due to reduced incentives. In equilibrium, share prices are identical to those implied by a model with no trade. Similarly, the monopolist buyer in Daley and Green (2018) who cannot commit to their future strategy gains nothing from their ability to screen buyers over time.

¹⁹ With no future debt issuance, the marginal cost to shareholders of an extra \$1 of debt is the present value of the after-tax debt payments until default (noting that the effect of any change in the timing of default is second order thanks to the envelope theorem), whereas the debt price is the present value of the pre-tax payments.

$$\begin{aligned}
-rp(Y, F) &= \pi'(Y - cF) \cdot c - (c + \xi) + \xi p(Y, F) + \xi F p_F(Y, F) \\
&\quad - \mu(Y) p_Y(Y, F) - \frac{1}{2} \sigma(Y)^2 p_{YY}(Y, F) + \lambda(Y) \left[-p(Y + \zeta(Y), F) + p(Y, F) \right].
\end{aligned} \tag{11}$$

Although equation (11) is written in terms of the debt price p , we emphasize that it follows mechanically from the equity valuation equation (9), together with the first-order condition (8) for the optimal issuance policy. Finally, adding (11) to (10), we obtain the following result on how to construct a smooth equilibrium and characterize the equilibrium debt issuance policy:

PROPOSITION III (EQUILIBRIUM CONSTRUCTION AND OPTIMAL ISSUANCE). *Suppose the no trade value $V^0(Y, F)$ is continuously differentiable and strictly convex in F (outside the default region).²⁰ Then $V = V^0$ is the unique smooth equilibrium value function, with debt issuance policy*

$$G^*(Y, F) = \frac{\pi'(Y - cF) \cdot c}{-p_F(Y, F)} = \frac{\pi'(Y - cF) \cdot c}{V_{FF}(Y, F)}. \tag{12}$$

Under this policy, the debt price given by (6) satisfies $p = -V_F$.

Proof: Given a smooth policy, (7) and (8) imply (11), which combined with (12) implies that $-V_F$ satisfies (10). Because further $p = -V_F = 0$ at the default boundary, we have that $p = -V_F$ satisfies (6). Finally, the global optimality of the issuance policy follows from $p = -V_F$ and the strict concavity of V . ■

While this result provides sufficient conditions for the existence of a smooth equilibrium and provides its characterization, it does not rule out non-smooth equilibria. We shall give conditions for the smooth equilibrium to be the unique MPE in Section II.

We can interpret the equilibrium debt issuance policy (12) as follows. The rate of issuance of debt is such that the rate of devaluation of the debt induced by new issuances just offsets the marginal tax benefit associated with the coupon payments:

$$-G^*(Y, F) p_F(Y, F) = \pi'(Y - cF) c. \tag{13}$$

²⁰ We note that a simple sufficient condition for convexity in F is a constant marginal tax rate (for a more general proof including investment see the proof of Error! Reference source not found.). Differentiability should follow given appropriate regularity conditions on the earnings process Y (and holds for standard models commonly used in finance).

Note that the debt issuance is strictly positive given the strictly positive marginal tax rate. Again, this result is consistent with the leverage ratchet effect of Admati et al. (2018)—even if the firm’s current leverage is excessive, equity holders never actively reduce debt but always have an incentive to increase debt when it provides a marginal tax benefit.

C.4 Discrete Optimization

In equilibrium, because $p = -V_F$, the value of equity is the same for *any* smooth issuance policy G . The equilibrium policy G^* is then uniquely determined so that the resulting debt price makes shareholders indifferent. In a sense, our characterization of G^* is analogous to that of a mixed strategy equilibrium in which each player is indifferent to her choice of action, yet equilibrium strategies are uniquely determined to maintain that indifference.

Shareholder indifference regarding the issuance policy is, however, an artifact of the continuous-time limit. If we were to compute the equilibrium as the limit of a discrete-time model, the optimal policy G^* would arise as the result of a strict optimization by shareholders. To see this result heuristically, suppose that the firm issues debt Δ which is fixed over the next dt instant, and let p and V be the end-of-period debt price and equity value functions, respectively. The firm would then pay additional interest of $\Delta c dt$, and thus its earnings would decline by $(1 - \pi'(Y - cF))\Delta c dt$ on an after-tax basis.²¹ Because the bonds trade for a cum-coupon price of $c dt + p(Y, F + \Delta)$, shareholders would choose Δ to solve:²²

$$\max_{\Delta} \underbrace{-(1 - \pi'(Y - cF))\Delta c dt}_{\text{after-tax interest payment}} + \underbrace{\Delta [c dt + p(Y, F + \Delta)]}_{\text{debt proceeds}} + V(Y, F + \Delta). \quad (14)$$

This maximization has the first-order condition

$$\Delta = \frac{\pi'(Y - cF)c dt + \overbrace{(p + V_F)}^{\text{zero by equilibrium condition (8)}}}{-p_F} = \frac{\pi'(Y - cF)c}{-p_F} dt, \quad (15)$$

²¹ Here we are ignoring terms of order dt^2 or higher, which would arise if the marginal tax rate is not locally constant.

²² Recall that p is the end-of-period bond price. If sold earlier it will trade for a higher price that includes the initial coupons. Also, we assume the new debt issuance occurs after the current period’s default decision and principal repayments; changing the timing would introduce terms of order dt^2 without altering the conclusion.

which exactly coincides with (12). Hence, we can interpret G^* as the strictly optimal issuance rate when the firm has “infinitesimal” commitment power over $[t, t + dt]$ in a discrete-time setting.²³

C.5 Summary

In sum, for the general model without commitment in which equity holders are free to issue or repurchase any amount of debt at the prevailing market price, one can solve for the smooth equilibrium as follows:²⁴

- (i) Use (9) to solve for the equity holder’s value function $V(Y, F) = V^0(Y, F)$ by setting $G = 0$ (i.e., as if equity holders commit not to issue any future debt).
- (ii) Set the debt price $p(Y, F) = -V_F(Y, F)$.
- (iii) Check for global optimality by verifying that, up to the point of default, the debt price $p(Y, F)$ is strictly decreasing in F (equivalently, V is strictly convex in F).
- (iv) Given $p(Y, F)$ solve for the equilibrium issuance policy $G^*(Y, F)$ from (12).

In the remainder of the paper we will use this methodology to analyze several standard settings and consider the consequence for debt valuation and leverage dynamics. We will also show that we can rule out any non-smooth Markov equilibria.

II. An Explicit Solution

We now apply the general methodology developed in the previous section to the widely used framework of a lognormal cash flow process and derive an explicit solution.²⁵ The results from Section I allow us to fully characterize an equilibrium in closed form and evaluate the corresponding leverage dynamics. We further extend the model to allow for jumps to cash flows,

²³ See also DeMarzo (2019) for additional discussion of the convergence from discrete to continuous time. Intuitively, if $p + V_F$ is $o(dt)$, then the per period gain from trade in (14) is $o(dt^2)$, and thus the gains do not aggregate in the limit.

²⁴ This general approach also applies to the case where shareholders make endogenous investment decisions along with leverage decisions, as shown in Section IV and explored further in the NBER working paper version <https://www.nber.org/papers/w22799>.

²⁵ This setting is consistent with, for instance, Merton (1974), Fischer et al. (1989), Leland (1994), and Leland and Toft (1996), and follows the development of starting from cash flows rather than firm value as in Goldstein et al. (2001).

show that the solution is qualitatively unchanged, and establish the uniqueness of the Markov equilibrium in this setting. Finally, Section D studies the case of a positive recovery value; shareholders' ability to restructure the debt to their advantage using the threat of dilution makes the debt price more sensitive to new issuance, thereby reducing the equilibrium level of debt.

A. Lognormal Cash Flows

In the special case of lognormal operating cash flow, Y_t follows a geometric Brownian motion:

$$\mu(Y_t) = \mu Y_t \text{ and } \sigma(Y_t) = \sigma Y_t, \text{ with } r > \mu. \quad (16)$$

To maintain homogeneity, we also assume a constant tax rate $\bar{\pi} > 0$ so that²⁶

$$\pi(Y_t - cF_t) = \bar{\pi} \cdot (Y_t - cF_t). \quad (17)$$

Given the scale invariance of the firm in this setting, the economically relevant measure of leverage is operating cash flow scaled by the outstanding face value of debt,

$$y_t \equiv Y_t / F_t, \quad (18)$$

which is proportional to the firm's *interest coverage ratio*—that is, the ratio of operating income Y_t to total interest expense cF_t —a widely used measure of leverage and financial soundness. (An alternative, equivalent characterization is given in terms of the debt-to-income ratio $f_t \equiv F_t / Y_t = 1 / y_t$.) Because all subgames with the same initial leverage y_t are strategically equivalent, we will look for a MPE in this uni-dimensional state variable, and show that it must be a smooth equilibrium.²⁷ That is, with this restriction, the smooth equilibrium is the unique MPE.

In this setting with scale-invariance, the equity value function $V(Y, F)$ and debt price $p(Y, F)$ satisfy

$$V(Y, F) = V\left(\frac{Y}{F}, 1\right)F \equiv v(y)F \text{ and } p(Y, F) = p\left(\frac{Y}{F}, 1\right) \equiv p(y). \quad (19)$$

²⁶ As with the existing literature, our model adopts an idealized version of the tax code. In practice, the debt tax shield is not strictly tied to the coupon rate, but includes an adjustment for any discount or premium at the time of issuance. In addition, tax shields may be deferred when earnings are negative.

²⁷ Here we follow Maskin and Tirole (2001), who argue for defining MPE in terms of the coarsest partition such that equivalent subgames are “strategically equivalent.” A sufficient condition for strategic equivalence is that the payoffs are equivalent up to an affine transformation (as is the case here).

We will solve for the (scaled) equity value function $v(y)$ and debt price $p(y)$ in closed form.

Given the evolution of our state variables Y_t and F_t :

$$dY_t = \mu Y_t dt + \sigma Y_t dZ_t, \text{ and } dF_t = (G_t - \xi F_t) dt, \quad (20)$$

the scaled cash flows evolve as

$$\frac{dy_t}{y_t} = (\mu + \xi - g_t) dt + \sigma dZ_t, \text{ where } g_t \equiv G_t/F_t. \quad (21)$$

As (21) shows, because the debt F_t grows in a locally deterministic way, the scaled cash flow grows with the same volatility as the total cash flow. The growth rate, however, is increased by the rate of debt amortization rate, ξ , net of the endogenous issuance rate, $g_t \equiv G_t/F_t$. The higher the rate of debt issuance, the slower the growth rate of the scaled cash flow.

When the scaled cash flow y_t falls below some endogenous default boundary y_b , equity holders are no longer willing to service the debt, and therefore choose to strategically default. In that event, we assume for now that both equity and debt holders receive zero liquidation value.

B. Model Solution

Recall from Section I that we can solve for the equilibrium equity value *as if* $g_t = 0$ and hence equity holders do not actively adjust the firm's debt, even though they will do so in equilibrium. Using the fact that

$$V_Y(Y, F) = v'(y), \quad V_F(Y, F) = v(y) - yv'(y), \text{ and } FV_{YY} = v''(y), \quad (22)$$

we can rewrite (9) with lognormal cash flows in terms of scaled cash flow y as follows:

$$(r + \xi)v(y) = (y - c - \xi) - \bar{\pi}(y - c) + (\mu + \xi)yv'(y) + \frac{1}{2}\sigma^2 y^2 v''(y). \quad (23)$$

Note that if the firm could not default, then the cash flows and debt payments could be evaluated as growing perpetuities. Thus, the no default value of equity would be

$$\bar{v}(y) \equiv \underbrace{\frac{1 - \bar{\pi}}{r - \mu} y}_{\text{unlevered asset value}} + \underbrace{\frac{\bar{\pi}c}{r + \xi}}_{\text{tax shield}} - \underbrace{\frac{c + \xi}{r + \xi}}_{\text{bond value}} \equiv \phi y - \rho, \quad (24)$$

where $\phi \equiv \frac{1-\bar{\pi}}{r-\mu}$ is the unlevered valuation multiple for the firm, and $\rho \equiv \frac{c(1-\bar{\pi})+\xi}{r+\xi}$ is the after-

tax cost to the firm of a riskless bond.²⁸ To compute the no trade equity value, we must add to \bar{v} the value of the default option. The next result characterizes the resulting value function, and establishes that this equilibrium is unique (smooth or otherwise).

PROPOSITION IV (EQUILIBRIUM WITH LOGNORMAL CASH FLOWS). *Given lognormal cash flows with constant tax rate $\bar{\pi}$, let*

$$\gamma \equiv \frac{(\mu + \xi - 0.5\sigma^2) + \sqrt{(\mu + \xi - 0.5\sigma^2)^2 + 2\sigma^2(r + \xi)}}{\sigma^2} > 0. \quad (25)$$

Then the unique Markov perfect equilibrium in y is the smooth equilibrium, with the equity value function and optimal default boundary given by

$$v(y) = \underbrace{\phi y - \rho}_{\text{no default value}} - \underbrace{\left(\frac{y}{y_b}\right)^{-\gamma} (\phi y_b - \rho)}_{\text{default option value} > 0} \text{ and } y_b = \frac{\gamma}{1+\gamma} \frac{\rho}{\phi}. \quad (26)$$

Proof: Given shareholders' option to default and receive zero, the no trade value function equals

$$v(y) = \bar{v}(y) + \underbrace{E^0 \left[e^{-(r+\xi)\tau_b} \right]}_{\text{default option value}} (0 - \bar{v}(y_b)), \quad (27)$$

where E^0 denotes the expectation given $g \equiv 0$. The discount factor $h(y) \equiv E^0 \left[e^{-(r+\xi)\tau_b} \right]$ must solve the homogeneous version of (23),

$$(r + \xi)h(y) = (\mu + \xi)yh'(y) + \frac{1}{2}\sigma^2 y^2 h''(y),$$

with boundary conditions $h(y_b) = 1$ and $h(\infty) = 0$, which is solved by $h(y) = (y/y_b)^{-\gamma}$. The optimal default boundary y_b maximizes the value of the default option and is determined by smooth-pasting, $v'(y_b) = 0$. Because v is smooth and strictly convex (prior to default),

PROPOSITION III implies that v is the equity value function in the smooth equilibrium with trade. We prove in the [appendix](#) that there does not exist any non-smooth MPE in y . ■

²⁸ The value \bar{v} is a particular solution to (23) that ignores the default boundary condition.

PROPOSITION IV establishes the unique equilibrium value function within the class of MPE given the firm’s interest coverage ratio (or debt-income ratio) measured by y . While it is possible to construct other, non-smooth equilibria if we allow the firm and investors to condition on non-strategically relevant variables (such as the firm’s absolute size or age), our equilibrium conforms with standard metrics used in practice to evaluate leverage and credit spreads.²⁹

Having solved for the value of equity, recall that we can determine the debt price from the first-order conditions (8). Using (22) and (26), we have

$$p(y) = -V_F = yv'(y) - v(y) = \rho \left(1 - \left(\frac{y}{y_b} \right)^{-\gamma} \right). \quad (28)$$

Note that the debt price is strictly increasing in y , and therefore strictly decreasing in F , as required in **PROPOSITION III**, which we can now apply (12) to derive the equilibrium debt issuance policy. As shown in the next proposition, the rate of debt issuance $g^*(y)$ is strictly positive, and increasing in the scaled cash flow y .³⁰

PROPOSITION V (EQUILIBRIUM DEBT ISSUANCE). *Given lognormal cash flows with constant tax rate $\bar{\pi}$, the no commitment debt price is given by (28), and the equilibrium rate of debt issuance is*

$$g^*(y) = \frac{G^*}{F} = \frac{\bar{\pi}c}{-Fp_F(Y, F)} = \frac{\bar{\pi}c}{yp'(y)} = \frac{\bar{\pi}c}{y^2v''(y)} = \frac{\bar{\pi}c}{\rho\gamma} \left(\frac{y}{y_b} \right)^\gamma. \quad (29)$$

Thus, with lognormal cash flows, we can fully characterize equilibrium debt dynamics and security pricing in closed form. The equity value equals the value without future trade, implying that shareholders do not benefit from their ability to issue debt in the future. Without commitment,

²⁹ Including additional state variables allows investors to “punish” the firm discontinuously—via a discrete jump in credit spreads that depends on variables other than leverage—for even minor deviations from a proposed equilibrium path. Restricting debt prices to be continuous in firm leverage would be an alternative means to rule out such equilibria. See Maskin and Tirole (2001) for a formalization of the idea that MPE embody the principle that “minor causes should have minor effects.” (See also footnote 27 as well as our concluding comments.)

³⁰ Note that g^* represents the issuance rate as a proportion of the current debt level F ; that is, total issuance is $G^* = Fg^*(y)$. And although $g^*(y) \rightarrow \infty$ as $F \rightarrow 0$, in Section III.A we will derive the debt dynamics explicitly starting from $F = 0$ and show that under the optimal policy the firm’s outstanding debt follows a continuous sample path with no jumps.

creditors anticipate future debt issuance at the rate given by (29), which depresses the current debt price. Indeed, as the following result demonstrates, the debt price falls by the value of the interest tax shield.

PROPOSITION VI (COMMITMENT VS. NO COMMITMENT DEBT PRICE). *Let $p^0(y)$ be the debt price if the firm committed not to issue future debt ($g = 0$). Then*

$$p^0(y) = p(y) + \underbrace{\frac{\bar{\pi}c}{r + \xi} \left[1 - \left(\frac{y}{y_b} \right)^{-\gamma} \right]}_{\text{debt tax shield value}}. \quad (30)$$

Proof: Because the equity value is unchanged, so is the default boundary y_b . Thus,

$$p^0(y) = \underbrace{\frac{c + \xi}{r + \xi}}_{\text{default-free value}} - \underbrace{E^0 \left[e^{-(r+\xi)\tau_b} \right]}_{\text{expected loss in default}} \frac{c + \xi}{r + \xi} = \frac{c + \xi}{r + \xi} \left(1 - \left(\frac{y}{y_b} \right)^{-\gamma} \right).$$

The result follows from comparison with (28). ■

Based on the equilibrium values for both equity and debt, total firm value (or total enterprise value, TEV) can be expressed as a multiple of the firm's cash flow (i.e., TEV to EBIT):

$$\frac{V(Y, F) + p(Y, F)F}{Y} = \frac{v(y) + p(y)}{y} = v'(y) = \phi \left[1 - \left(\frac{y}{y_b} \right)^{-\gamma-1} \right], \quad (31)$$

where the second equality follows from the equilibrium condition for the debt price, and the last equality uses the solution for y_b from (26).

The firm's TEV multiple is strictly increasing with the scaled cash flow y , and thus, total firm value *decreases* with leverage. Although there are tax benefits associated with debt, the firm issues debt aggressively enough that the cost of debt rises to offset the tax benefits. In equilibrium, the tax benefits of leverage are fully dissipated by the increase in expected default costs due to continued borrowing. This result is in stark contrast to standard tradeoff theory models, such as Leland (1994), in which it is optimal for the firm to issue a large block of debt immediately. In these models, the firm is able to capture a tax benefit only because of its assumed commitment not to issue additional debt.

C. Cash Flow Jumps

In the no commitment equilibrium, the firm's debt level evolves continuously according to (29). Ostensibly, the smooth issuance policy might seem to depend on the continuity of cash flows and asset values in the diffusion setting. In this section, however, we extend our model to allow the firm's cash flows to jump discontinuously, for example in response to new product development, and show that our prior solution, in which shareholders issue debt smoothly, is essentially unchanged.

Consider a jump-diffusion model in which cash flows occasionally jump from Y_t to θY_t for some constant $\theta > 1$.³¹ Specifically,

$$dY_t = \hat{\mu} Y_t dt + \sigma Y_t dZ_t + (\theta - 1) Y_{t-} dN_t, \quad (32)$$

where $\hat{\mu}$ is a constant and dN_t is a Poisson process with constant intensity $\lambda > 0$. In this extension, due to upward jumps, the effective expected asset growth rate becomes

$$\mu \equiv \hat{\mu} + \lambda(\theta - 1), \quad (33)$$

and we continue to assume $\mu < r$ to ensure that the unlevered firm value is bounded. Our later comparative static analysis in jump parameters holds the effective growth rate μ fixed.

As before, we can solve for the equity value as if shareholders commit not to issue any new debt. Because (32) still maintains scale invariance, $V(Y, F) = F \cdot v(y)$ continues to hold, and the HJB equation for the equity value becomes

$$(r + \xi)v(y) = (1 - \bar{\pi})(y - c) - \xi + (\hat{\mu} + \xi)yv'(y) + \frac{1}{2}\sigma^2 y^2 v''(y) + \lambda(v(\theta y) - v(y)). \quad (34)$$

The last term in equation (34) captures upward jumps. The usual boundary conditions apply: when $y \rightarrow \infty$ and thus leverage is negligible, default risk disappears and $v(y) \rightarrow \bar{v}(y)$; while at the point of default, we have value-matching $v(y_b) = 0$ and smooth-pasting $v'(y_b) = 0$.

³¹ While we focus on upward jumps with a fixed size, allowing the upward jump to be stochastic is straightforward. Downward jumps ($\theta < 1$) introduce an extra complication due to jump-triggered default, in addition to diffusion-triggered default. The analysis in Chen and Kou (2009) suggests that one can still solve for the equity valuation in closed form under certain conditions. In any case, our qualitative result hold as long as the equity value function remains convex.

Our next result shows that even with jumps, equilibrium security prices and debt dynamics have exactly the same functional form we derived in the diffusion-only case, and that this smooth equilibrium is the unique MPE in state variable y :

PROPOSITION VII (EQUILIBRIUM WITH CASH FLOW JUMPS). *Suppose cash flows evolve as a lognormal diffusion with upward jumps as in (32), with $\hat{\mu} = \mu - \lambda(\theta - 1)$ from (33). Then there exists a unique MPE in y , for which the equity value, debt price, and issuance policy are given by (26), (28), and (29) respectively, with γ the unique positive root of*

$$W(\gamma) = \lambda\theta^{-\gamma} + \frac{1}{2}\sigma^2\gamma^2 - \left(\mu - \lambda(\theta - 1) + \xi - \frac{1}{2}\sigma^2\right)\gamma - (r + \xi + \lambda) = 0. \quad (35)$$

Given parameters $(\mu, \xi, r, \sigma, \lambda, \theta)$, the solution γ is increasing in (μ, ξ, r) and decreasing in $(\sigma, \lambda, \theta)$. Holding the growth rate μ fixed, the reduction in γ from an increase in $(\sigma, \lambda, \theta)$ raises the value of equity via the default option.

Proof: See the [Appendix](#). ■

Thus, an increase in jump frequency or size changes the value of equity similarly to an increase in volatility. Surprisingly, however, even if the firm's profitability Y_t jumps discretely, the equilibrium debt issuance policy (29) continues to hold and debt issuance remains smooth (that is, of order dt). Thus, in response to a jump in profits, leverage falls discretely before gradually mean-reverting due to a higher speed of issuance. This property holds even if $\sigma^2 \rightarrow 0$ so that the firm's cash flows grow *only* with discrete jumps.³²

D. Positive Recovery with Pari Passu Debt

Thus far we have assumed that in the event of default the liquidation value of the firm is zero. Under this assumption, there is no difference between junior and senior debt, which rules out any direct dilution motive for issuing debt. Existing creditors are nonetheless harmed by the issuance of new debt due to its effect on the timing of default.

³² When $\sigma^2 = 0$, we assume $\hat{\mu} + \xi < 0$ so that, between jumps, cash flows decline faster than debt matures. Absent this assumption, the firm can sustain 100% debt financing without risking default, and the first-best can be obtained. See DeMarzo (2019) for further details.

In this section we restrict attention to pari passu debt and consider the possibility that the firm may have a strictly positive liquidation value in default.³³ While the firm’s current creditors might hope to recover these liquidation proceeds, shareholders have an incentive to dilute their claim by issuing new debt prior to default. Indeed, given current debt F , shareholders could capture the fraction $\Delta / (F + \Delta)$ of any recovery value by issuing new debt with a face value of Δ and equal priority just prior to default and then using the proceeds to pay a dividend. Thus, by issuing an arbitrarily large block of debt just prior to default, shareholders could obtain the entire liquidation value, leaving existing creditors with zero recovery if they have no ability to restrict issuance.³⁴

In practice, creditors will naturally try to block such extreme dilution by attempting to seize assets, block shareholder payouts, and disrupt operations. Shareholders, in turn, may choose to liquidate assets to fund ongoing operations, or engage in asset substitution, in order to gamble for resurrection. Shareholder-creditor conflicts throughout this process are likely to sacrifice efficiency and reduce the ultimate recovery value that can be achieved.³⁵ Often, the resolution of default or distress is a restructuring in which both creditors and shareholders retain some value. Rather than model this complexity directly, in this section we adopt a stylized reduced-form approach which can be calibrated to empirical data to allow for a tradeoff between creditor recovery and efficiency.

Suppose there are alternative bankruptcy or restructuring regimes shareholders may adopt, indexed by $j \in J$, which differ in terms of creditors’ expected recovery rate, $\beta_j \geq 0$, and expected efficiency, measured by the fraction of the firm’s unlevered value $\alpha_j \geq 0$ that is preserved. That is, in regime j , creditors receive a total expected payoff of $\beta_j \rho F$, while shareholders capture the

³³ See DeMarzo (2019) for an analysis including senior secured debt. In that case, the firm can capture tax benefits associated with its collateralized debt.

³⁴ In other words, there would be a complete violation of absolute priority so that equity holders receive the entire recovery value of the firm (while debt holders recover nothing). Moreover, this dilution can be accomplished at the moment of default—there is no need for the firm to issue debt for the purpose of dilution beforehand. In contrast, Dangl and Zechner (2016) consider pari passu debt with positive recovery, but constrain the rate of debt issuance. Because of this constraint, shareholders issue debt at the maximum speed possible for some period prior to default.

³⁵ In Section IV we consider endogenous investment/disinvestment, which introduces an additional source of shareholder-creditor conflict.

expected residual value of the firm net of the creditors payoff, $\alpha_j \phi Y - \beta_j \rho F$.³⁶ We assume that one possible outcome (regime 0) is that, as in Section A, shareholders and creditors refuse to agree until all surplus is destroyed ($\alpha_0 = \beta_0 = 0$).³⁷ Alternative regimes—such as renegotiating or restructuring the debt prior to default, or Chapter 11 versus Chapter 7 bankruptcy proceedings—may differ in terms of their efficiency and degree of creditor protections. More generally, the parameters (α, β) capture in reduced form the consequences of some subgame in which shareholders and creditors adapt their behavior in response to leverage (e.g., in Section III we will endogenize these parameters in a setting with underinvestment due to debt overhang; we could also consider a setting in which shareholders inefficiently continue the firm and gamble for resurrection).

Given the available alternatives, shareholders choose the default or restructuring regime to maximize their payoff,

$$v^B(y) \equiv \max_{j \in J} \alpha_j \phi y - \beta_j \rho. \quad (36)$$

Compared to our initial setting, shareholders now choose both the timing and the mode of default. The existence of restructuring regimes which retain some firm value provides shareholders with an additional strategic option, and this potentially enhances shareholder value and changes the cash flow threshold at which default will occur.

PROPOSITION VIII (EQUILIBRIUM WITH RECOVERY). *In the unique MPE in y , shareholders will choose the default regime j^* that solves*

$$\Lambda_j = \max_{j \in J} \frac{(1 - \beta_j)^{\gamma+1}}{(1 - \alpha_j)^\gamma} \geq 1. \quad (37)$$

³⁶ We normalize the face value of debt by $\rho \equiv \frac{c(1 - \bar{\pi}) + \xi}{r + \xi}$ to account for the fact that the initial debt price (even

with zero leverage) may differ from par. This normalization simplifies expressions but is not otherwise consequential.

³⁷ We have already seen that by threatening to dilute existing creditors, shareholders can drive down their recovery rate (β_0) to zero. The assumption $\alpha_0 = 0$ presumes creditors can also block payouts to shareholders. When $\alpha_j > 0$ shareholders may receive something from the restructuring.

The equity value function and optimal default boundary are

$$v^J(y) = \underbrace{\phi y - \rho - \Lambda_J \left(\frac{y}{y_b} \right)^{-\gamma}}_{\text{default option value}} (\phi y_b - \rho) \quad \text{and} \quad y_b^J = \frac{1 - \beta_{j^*}}{1 - \alpha_{j^*}} y_b \geq y_b. \quad (38)$$

The equilibrium debt price and rate of debt issuance are given by

$$p^J(y) = \rho \left(1 - \Lambda_J \left(\frac{y}{y_b} \right)^{-\gamma} \right) \quad \text{and} \quad g^*(y) = \frac{\bar{\pi}c}{\Lambda_J \rho \gamma} \left(\frac{y}{y_b} \right)^\gamma. \quad (39)$$

Proof: See the [Appendix](#). ■

PROPOSITION VIII demonstrates the tradeoff between efficiency and debt recovery in restructuring as a function of the parameter γ , which depends on the firm's volatility, growth rate, and debt maturity according to (25) (or, in the case with jumps, (35)). The endogenous parameter $\Lambda_J \geq 1$, which takes the value of 1 for the baseline case $\alpha_0 = \beta_0 = 0$, fully characterizes the impact of this decision on the equity and debt values. The existence of restructuring regimes with $\Lambda_J > 1$ increases efficiency and raises the value of equity. On the other hand, the threat of dilution makes the debt price (and total firm value) more sensitive to leverage, causing the equilibrium rate of debt issuance to decline proportionally with Λ_J .

The option to restructure will raise the default threshold to $y_b^J \geq y_b$. If y_b^J is high enough, the firm may restructure even before cash flows become negative.³⁸ In that case, in equilibrium the firm never requires access to equity capital (as it does in the standard Leland (1994) model).

III. Debt Dynamics

Now that we have solved for the equilibrium debt issuance policy and security pricing, we can analyze the implications for observed debt dynamics. Although lack of commitment leads the firm to always have a positive rate of debt issuance, the countervailing effects of debt maturity and asset

³⁸ The firm will have positive earnings at the time of restructuring if $\frac{1 - \beta_{j^*}}{1 - \alpha_{j^*}} \geq \left(\frac{1 + \gamma}{\gamma} \right) \left(\frac{r + \xi}{r - \mu} \right)$. Even if this condition

is not met, the firm may have positive cash flows once the debt proceeds $g^*(y_b^J) \beta_{j^*} \rho$ are included.

growth cause leverage to mean-revert gradually towards a target. We begin by characterizing this target as well as the speed of adjustment. We then consider the implications of alternative debt maturities. While the firm’s target leverage and rate of adjustment are greatly affected by maturity, we show that shareholders are indifferent to any maturity structure for future debt issuance. Thus, similar firms that are both maximizing shareholder value may nonetheless display very different debt dynamics. We conclude by considering welfare implications of debt maturity, as well as several low-leverage puzzles.

A. *Target Leverage and Adjustment Speed*

As shown in Section II, the equilibrium debt issuance rate $g^*(y)$ is faster when cash flows are high, and slows as the firm approaches default. Because the mapping is monotonic, there is a unique level of scaled cash flow y_ξ^* such that the equilibrium issuance rate will equal the rate of debt maturity:

$$g^*(y_\xi^*) \equiv \xi. \quad (40)$$

We can also interpret $f_\xi^* \equiv 1/y_\xi^*$ as the firm’s leverage “target,” the ratio of debt to earnings at which new issuance exactly balances the retirement of existing debt, leaving the firm’s total indebtedness unchanged. Over time, leverage will mean-revert towards this target level.³⁹

Figure 2 illustrates the net rate of debt issuance, given different debt maturities and asset volatilities, as a function of the firm’s debt-to-value ratio. Shorter debt maturity increases the speed of mean reversion, but has a non-monotonic impact on the target level of leverage. Lower volatility, on the other hand, raises both the target level of leverage and the speed of adjustment.

³⁹ Note that if the debt is perpetual or its maturity is very long so that $\xi \approx 0$, then $y_\xi^* < y_b$. In that case the firm’s total indebtedness F_t will strictly increase over time (prior to default).

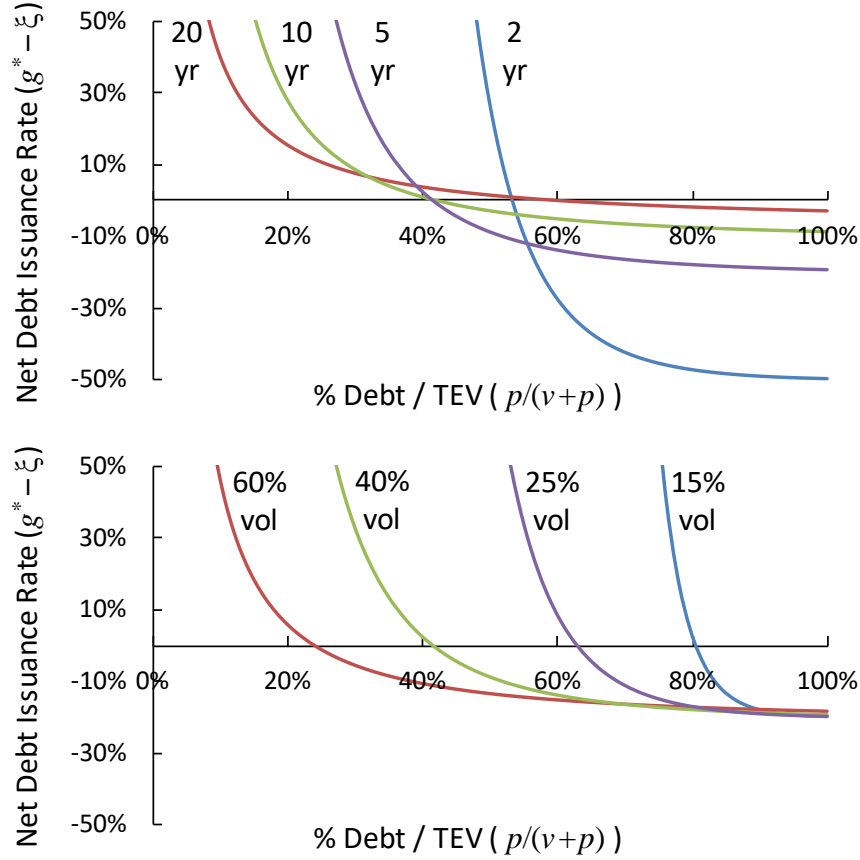

Figure 2: Net Debt Issuance versus Firm Leverage for Different Maturities and Volatilities

Baseline Parameters: $\mu = 2\%$, $\sigma = 40\%$, $\bar{\pi} = 30\%$, $c(1 - \bar{\pi}) = r = 5\%$, $\xi = 20\%$, $\lambda = 0$, $\Gamma_j = 1$

In our model the firm's debt is path dependent, with the current level of debt equal to the firm's cumulative past issuance net of its debt retirement. Because the issuance rate varies with the level of cash flows, this path dependence can be quite complex. Somewhat surprisingly, we can derive the evolution of the firm's debt explicitly as a function of the firm's initial debt position and its earnings history, as shown next.

PROPOSITION IX (DEBT EVOLUTION). Let $f_\xi^* \equiv 1/y_\xi^*$ be the firm's target ratio of debt to earnings. Given the debt issuance policy g^* and any initial debt face value $F_0 \geq 0$, the firm's debt on date t given the cash-flow history $\{Y_s : 0 < s < t\}$ is

$$F_t = \left[F_0^\gamma e^{-\gamma\xi t} + \gamma\xi \int_0^t e^{\gamma\xi(s-t)} (f_\xi^* Y_s)^\gamma ds \right]^{1/\gamma}. \quad (41)$$

Equivalently, for $dt \approx 0$,

$$F_{t+dt}^\gamma = (f_\xi^* Y_t)^\gamma (\gamma \xi dt) + F_t^\gamma (1 - \gamma \xi dt). \quad (42)$$

Proof: Recall from (39) and (40) that

$$g^*(y) = \frac{\bar{\pi}c}{\Lambda_J \rho \gamma} \left(\frac{y}{y_b} \right)^\gamma \quad \text{and} \quad \xi = g^*(y_\xi^*) = \frac{\bar{\pi}c}{\Lambda_J \rho \gamma} \left(\frac{y_\xi^*}{y_b} \right)^\gamma.$$

Then (41) and (42) are equivalent to

$$\frac{\frac{d}{dt} F_t}{F_t} = \frac{1}{\gamma} \frac{\frac{d}{dt} F_t^\gamma}{F_t^\gamma} = \frac{1}{\gamma} \frac{\gamma \xi (f_\xi^* Y_t)^\gamma - \gamma \xi F_t^\gamma}{F_t^\gamma} = \xi \left(\frac{y_t}{y_\xi^*} \right)^\gamma - \xi = \frac{\bar{\pi}c}{\Lambda_J \rho \gamma} \left(\frac{y_t}{y_b} \right)^\gamma - \xi = g^*(y_t) - \xi.$$

This evolution of debt matches (20) with $G_t = g^*(y_t) F_t$. ■

Equation (41) implies that the firm's debt today is a type of “discounted moving average” of the firm's initial debt and a target multiple f_ξ^* of the firm's intervening cash flows. This point becomes transparent in the special case of an initially unlevered firm. Setting $F_0 = 0$ in (41), we have

$$F_t = f_\xi^* \left(\gamma \xi \int_0^t e^{\gamma \xi (s-t)} Y_s^\gamma ds \right)^{1/\gamma}. \quad (43)$$

Because $\gamma \xi \int_0^t e^{\gamma \xi (s-t)} ds = 1 - e^{-\gamma \xi t} \approx \gamma \xi t$ for small t , debt grows gradually with order $t^{1/\gamma}$ for an initially unlevered firm, while the firm's long-run debt level depends on the weighted average of its historical earnings.⁴⁰

In the equilibrium debt dynamics, the weight put on recent cash flows relative to more distant ones is an increasing function of the product $\gamma \xi$. Equivalently, as (42) makes clear, the product $\gamma \xi$ determines the speed of adjustment toward the target level. Intuitively, shorter debt maturity (higher ξ) implies faster repayment of debt principal, allowing leverage to shrink more quickly in the face of declining cash flows. From (35), γ increases with shorter maturity, higher growth, or lower volatility, making the firm more aggressive in adding leverage in response to

⁴⁰ This continuous debt increment at $F_0 = 0$ is consistent with the infinite growth rate of $g^*(y)$ as $y \rightarrow \infty$.

positive cash flows news. Finally, note from (39) that the only impact of the tax rate $\bar{\pi}$ or the default regime (via $\Lambda_j \geq 1$) is on the target debt-to-income level f_ξ^* .⁴¹

PROPOSITION IX demonstrates that once the firm is free to adjust leverage over time, equilibrium debt dynamics depart strongly from the predictions of the standard dynamic tradeoff theory literature. In particular, our result that debt slowly but continuously adjusts towards a target leverage level differs from the models in which debt levels are fixed initially (say, Leland 1994, 1998), or jump periodically due to fixed adjustment costs (say, Goldstein, Ju, and Leland, 2001). Figure 3 simulates the evolution of debt of different maturities for an initially unlevered firm. In each case in this ten-year sample path, the shocks to earnings, and therefore the unlevered value of the firm, are the same.

The top panel of Figure 3 shows that the initial impact of these alternative debt maturities on total enterprise value is slight, with differences only emerging later when leverage becomes high. The slow adjustment of total debt in the middle panel highlights the long persistence and hysteresis in debt levels. This speed of adjustment declines with the debt maturity. Finally, the bottom panel it makes clear that the primary driver of market leverage in the short term is due to fluctuation in the stock price.

⁴¹ Indeed, the target debt level decreases with Λ_j , as the increase in the value of the shareholders' default option comes at creditors' expense, lowering the debt price. The target debt ratio f_ξ^* increases with the tax rate if the debt maturity is long ($\xi \approx 0$). But if the debt maturity is short and tax rates are high, a tax increase may raise the default boundary y_b sufficiently to cause the target debt-to-income ratio to fall.

Figure 3: Simulation of Debt Evolution

Evolution of firm value and debt level for different debt maturities. Top panel shows TEV. Middle panel shows debt level versus unlevered value $V^U = \phi Y$. Bottom panel shows market leverage (with legend indicating target). Note that two-year debt defaults in year 5.

($\mu = 2\%$, $\sigma = 40\%$, $\bar{\pi} = 30\%$, $c(1 - \bar{\pi}) = r = 5\%$, $\xi = 5\%, 10\%, 20\%, 50\%$)

These features resemble the evolution of debt most commonly observed in practice.⁴² Our model hence provides a theoretical foundation for partial adjustment models (Jalilvand and Harris, 1984; Leary and Roberts, 2005; etc.) that are widely used in the empirical capital structure literature. Gradual “under-adjustment” also leads to the well-documented negative relation between leverage and profitability, even for frequent issuers of debt (see Frank and Goyal 2014 and Eckbo and Kissner 2018).

Consider, for example the case of five-year debt. While the target level of market leverage is 42%, the firm does not issue this amount immediately. Debt increases quickly at first, but is soon outpaced by increases in firm value. When firm value declines after year four, leverage overshoots the target, as the firm can reduce leverage no faster than its debt matures. On the other hand, with two-year debt, the firm adjusts quickly to a target leverage ratio of 53%, and increases leverage significantly as firm value grows. But when firm value declines sharply in year five, the firm is unable to reduce leverage quickly enough and the firm defaults. Finally, with twenty-year debt, although the target leverage ratio is 60%, the speed of adjustment is very slow, and the firm gradually increases debt over the entire ten-year period.

B. Debt Maturity Indifference

Our model considers a constant maturity structure in which all debt has an expected maturity of $1/\xi$. This assumption is common in much of the dynamic capital structure literature which treats the debt maturity structure as a parameter.⁴³ While it is beyond the scope of this paper to allow the firm full flexibility over maturity structures, we show that absent commitment, shareholders are indifferent to the maturity structure of the firm’s future debt issuance. While different maturity choices will lead to different future leverage levels, any increase in tax benefits is offset by an increase in default costs, and the firm’s current share price is unaffected.

⁴² For example, Welch (2004) reports that market leverage changes primarily due to stock price fluctuations, and Baker and Wurgler (2002) document that the firm’s current leverage depends on its equity price over the past decade or more. Graham and Leary (2011) survey a number of studies which suggest an annual speed of adjustment towards a target leverage ratio of between 10% and 40%. Frank and Shen (2019) report that allowing for heterogeneity in the determination of leverage targets leads to much faster estimates of the mean-reverting adjustment speed.

⁴³ Debt retirement in this fashion is similar to a sinking fund that continuously buys back debt at par; see Leland (1998), Leland and Toft (1996), He and Xiong (2012), and Diamond and He (2014). See, however, Brunnermeier and Oehmke (2013) and He and Milbradt (2016) for analysis of the firm’s decision to lengthen or shorten its debt maturity.

Recall from **PROPOSITION II** that we can compute the current value of equity as though the firm will not issue or repurchase debt in the future and will just repay its existing debt as it matures. This result immediately implies that for an initially unlevered firm ($F_0 = 0$), firm value does not depend on the choice of debt maturity structure ξ . This irrelevance result can be generalized further. Consider the following thought experiment, in which shareholders—facing the current cash flows and debt structure (Y_t, F_t, ξ) —have a one-time opportunity to choose an alternative maturity ξ' for the firm's *future* debt. That is, the firm's existing debt continue to retire at the old speed ξ , but the newly issued debt retires at the new speed ξ' . We have the following proposition.

PROPOSITION X (MATURITY INDIFFERENCE). In a no-commitment equilibrium with smooth debt issuance, the firm's current equity value is independent of the maturity ξ' of new debt.

Proof: See the [Appendix](#). ■

The intuition for the proof is straightforward. We can consider the implied future liabilities from the firm's existing debt as a modification of the cash flow process for the firm and then apply our general methodology as in Section I. For equilibria with smooth debt issuance policies, equity holders obtain zero profit by issuing future debt, and so the equity value would be the same as if the firm could not issue future debt. As a result, the current equity value only depends on the maturity structure ξ of existing debt, but not on the maturity structure ξ' of future debt. This logic and hence the indifference result can be further generalized to a setting in which the firm is free to choose any maturity structure for its newly issued debt any time. Again, the equity value will only depend on the maturity structure of the firm's existing debt.

The indifference result can also be seen in Figure 3. Although the debt maturity choice leads to large differences in the evolution of debt and market leverage over time, the initial enterprise value of the firm is the same, and is equal to the unlevered firm value in all four cases.

Figure 3 also provides a potential explanation for the finding in Lemmon, Roberts, and Zender (2008) that much of the cross-sectional variation in firms' capital structure is persistent and largely unexplained by observable characteristics. From the perspective of our model, small perturbations or frictions that may lead firms to pick different initial maturity structures will lead

over time to dramatically different leverage outcomes. See also DeMarzo (2019) for further discussion of this point together with the potential role of collateral.

C. *Optimal Maturity: Price Impact and Welfare*

In the previous section, we demonstrated that the firm's shareholders are indifferent to the choice of debt maturity when debt issuance is unconstrained. This indifference result regarding debt maturity runs counter to the standard intuition that shareholder-creditor conflicts are ameliorated with short-term debt. While this intuition would hold if shareholders could commit ex-ante to maintain a given leverage policy,⁴⁴ our analysis shows that without commitment this intuition is not correct: the use of short-term debt induces the firm to lever more aggressively, and the agency costs resulting from the leverage ratchet effect do not disappear. Indeed, as maturity shortens to zero ($\xi \rightarrow \infty$), the firm's target leverage y_{ξ}^* converges to the default boundary y_b , increasing the firm's tax shields while solvent but keeping the firm ever closer to default. Intuitively, as long as opportunities to trade are sufficiently frequent relative to the maturity of the debt, leverage ratchet dynamics will emerge to reduce the gains from trade.⁴⁵

In this section, we show that a benefit of short-term debt reemerges if the firm is constrained to raise a fixed amount of initial debt. But although short-term debt may be privately optimal, it may be inefficient from the perspective of social welfare.

C.1 *Constrained Borrowing*

We have assumed throughout that the firm has frictionless access to both debt and equity markets, and shown that debt issuance will occur gradually over time. Suppose instead the firm is forced to raise a fixed amount of capital using debt.⁴⁶ In that case, which choice of debt maturity would shareholders prefer?

⁴⁴ See Tserlukevich (2008) for further elaboration of this point with commitment. The flexibility offered by short-term debt is also studied in a recent paper by Geelen (2017).

⁴⁵ Given any fixed maturity $1/\xi > 0$ with continuous trading, there is always the opportunity to issue new debt before the existing debt matures. The same issues arise even in a discrete time model, as long as new debt can be issued on the same date as the original debt; Bizer and DeMarzo (1992) demonstrate the agency cost associated with sequential rounds of simultaneous borrowing even in a one period model.

⁴⁶ For example, suppose the firm requires capital to launch, and is restricted from using all equity financing due to governance concerns, illiquidity, or other temporary costs outside the model.

As we have already shown, the convexity of the equity value function in F implies that issuing a large block of debt is costly to shareholders. This cost arises because the firm faces a downward-sloping demand (i.e., $p_F < 0$) for its debt. The price sensitivity of the debt, however, increases with the debt's maturity; because the initial debt issuance will not be actively unwound (due to the leverage ratchet effect), long maturity debt with a slower passive retirement speed will be more subject to future dilution. We confirm this result in Figure 4, which shows the drop in total firm value (TEV) for a given initial amount borrowed as a fraction d of the firm's unlevered value:

$$d = \frac{p(Y_0 / F)F}{\phi Y_0} = \frac{p(y_0)}{\phi y_0}.$$

Not only does short-term debt reduce the cost to firm value, it also increases the firm's debt capacity—the maximum amount it is able to borrow—which is restricted because at a high level of debt, the negative price impact from raising the face value more than offsets the increase in quantity.⁴⁷

Figure 4: Debt and Firm Value with Differing Maturities.

If the firm must borrow a fixed amount, using short-term debt raises its debt capacity and reduces the cost to firm value. Parameters are $\mu = 2\%$, $\sigma = 40\%$, $\bar{\pi} = 30\%$, $c(1 - \bar{\pi}) = r = 5\%$.

⁴⁷ See the NBER working paper version <https://www.nber.org/papers/w22799> where we formally establish this result and show that the debt capacity approaches 100% as $\xi \rightarrow \infty$. Of course, we have ignored other potential costs associated with short-term debt, such as rollover risk (see e.g., He and Xiong, 2012).

C.2 Maturity and Welfare

The result that shareholders are indifferent regarding debt maturity given smooth issuance must imply that the expected tax benefits of new debt are exactly offset by the increase in default costs borne by shareholders. But from a social planner's perspective, tax shields represent transfers, while bankruptcy costs reflect dead-weight losses which directly hurt welfare. Therefore, even if shareholders are indifferent to maturity, there will be a clear ranking in terms of expected welfare: choices that lead to higher expected tax benefits also imply higher expected default costs, and hence lower welfare.

We can use our model to calculate the expected future bankruptcy costs as a fraction of the current unlevered firm value, which we denote by $BC(y)$. Starting with initial debt F_0 , debt evolves according to $dF_t = (g(y_t) - \xi)F_t dt$ and default occurs at τ_b with $Y_{\tau_b} = y_b F_{\tau_b}$, with a loss equal to the firm's unlevered value at that time. Thus,

$$BC(y) = \frac{1}{\phi Y_0} \mathbb{E} \left[e^{-r\tau_b} \phi Y_{\tau_b} \mid Y_0 = yF_0, F_0 \right] = \frac{y_b}{y} \mathbb{E} \left[\exp \left(\int_0^{\tau_b} (g(y_t) - \xi - r) dt \right) \mid y_0 = y \right].$$

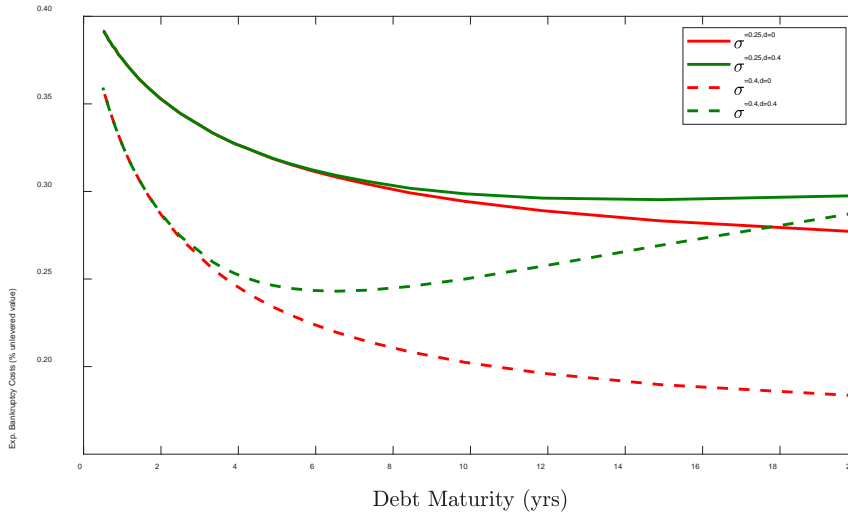

Figure 5. Expected Bankruptcy Costs BC (as a Fraction of Unlevered Firm Value).

For an initially unlevered firm ($d = 0$), expected bankruptcy costs decrease with both maturity and volatility, due to a slower issuance rate. But if the firm must borrow 40% of its unlevered value upfront ($d = p(y) / (\phi y) = 0.4$), then welfare is maximized for an intermediate debt maturity. Parameters are $r = c(1 - \bar{\pi}) = 5\%$, $\mu = 2\%$, $\bar{\pi} = 30\%$.

We compute $BC(y)$ for alternative debt maturities in Figure 5.⁴⁸ For an initially unlevered firm, expected bankruptcy costs are higher if the debt maturity is shorter (i.e., both red curves decline with debt maturity). The intuition for this result is that, as we saw in Figure 3, with short-term debt the firm takes on debt more quickly and maintains higher leverage over time, taking greater advantage of interest tax shields but also leading to a higher risk of default. Interestingly, as the figure also shows, lower firm volatility also gives rise to greater expected bankruptcy costs (i.e., the dashed lines sit below the solid lines). The key to this counterintuitive result is the endogenous debt issuance policy. Shareholders in a firm with lower volatility are more aggressive in leveraging up, so much so that we have greater expected bankruptcy costs.

Figure 5 also reveals that if the firm is constrained to borrow an initial fraction $d \in [0,1]$ of its unlevered value, then an intermediate debt-maturity will maximize welfare (i.e., the green curves are minimized at an interior point). This is because in the case of constrained initial borrowing, Figure 4 shows that given an initial borrowing requirement, longer-term debt leads to a larger initial welfare loss *even for shareholders* (that is, expected bankruptcy costs exceed tax benefits), and shareholders prefer to issue short-term debt. The social planner, however, only cares about bankruptcy costs. Intermediate maturity debt minimizes default costs by starting the firm further away from default than longer-term debt (given a fixed initial amount raised, as shown in Figure 4), while at the same time reducing the aggressiveness with which it will issue debt in the future compared to short-term debt.

D. Low Leverage Puzzles

Two important empirical observations associated with leverage are the credit-spread puzzle and the zero-leverage puzzle. As we discuss below, the implications of our model for debt dynamics and pricing can help to resolve both of these apparent anomalies.

⁴⁸ We compute BC numerically by defining $H(y) \equiv y \cdot BC(y)$, and noting that H satisfied the ODE,

$$(r + \xi - g(y))H(y) = (\mu + \xi - g(y))yH'(y) + 0.5\sigma^2 y^2 H''(y),$$

with boundary conditions $BC(y_b) = 1$ and $BC(y) \rightarrow k$ when $y \rightarrow \infty$ for some constant $k \in (0,1)$.

D.1 The Credit-Spread Puzzle

As Huang and Huang (2012) and others have observed, firms with low leverage often have much higher credit spreads than would be predicted by a standard structural models. In the context of our model, large credit spreads arise even for firms with low leverage because the debt is priced in anticipation of future debt issuance.

To see this effect, define the credit spread $\delta(y)$ as the yield spread required to match the bond's price absent default:

$$\frac{c + \xi}{r + \delta(y) + \xi} \equiv p(y), \text{ or equivalently, } \delta(y) \equiv \frac{c + \xi(1 - p(y))}{p(y)} - r. \quad (44)$$

As a comparison, we can also define the credit spread $\delta^0(y)$ that would apply in a model in which the firm commits not to issue more debt, by replacing $p(y)$ with $p^0(y)$ from (30) in the above definition.

It is easy to see that as leverage falls (y increases), both credit spreads decline. But as we approach zero leverage ($y \rightarrow \infty$), the credit spread with commitment vanishes ($\delta^0(y) \rightarrow 0$), whereas in the no commitment case,

$$\lim_{y \rightarrow \infty} \delta(y) = \frac{\bar{\pi}c}{\rho} > 0. \quad (45)$$

In other words, even with very low leverage, we should expect significant credit spreads in our model. The reason, of course, is that even when the firm's current debt level is very low, the future debt level is likely to be much higher given the mean-reverting leverage dynamics.

D.2 The Zero-Leverage Puzzle

Another significant empirical puzzle for the standard tradeoff theory is that despite the tax benefits of debt, there exist a larger number of firms with zero leverage, as documented by Strebulaev and Yang (2013).

At first glance, this fact would also appear to contradict our model, in which firms issue debt repeatedly. However, our equilibrium dynamics and the uniqueness result of Section II only apply in the range $y = Y/F < \infty$, and therefore $F > 0$. When $F = 0$, there are actually two

possible Markov perfect equilibrium outcomes: the firm can begin issuing debt, as in our model, or the firm can remain with zero-leverage. In either case, the payoff to shareholders is the same – they receive the unlevered value of the firm.

The zero-leverage equilibrium can exist because without commitment the firm is unable to capture the tax shield benefits of debt. As equation (45) shows, the initial credit spread on the debt is sufficient to offset the tax benefits. But, this no trade equilibrium disappears once debt is in place. The reason is that, in order for the price of the firm's outstanding debt to be consistent with equilibrium, the firm must be expected to continue to issue debt. This equilibrium constraint does not apply when $F = 0$, as there is no outstanding debt price.

IV. Endogenous Investment and Debt Overhang

We now extend our model by adding an endogenous investment decision also under the control of shareholders. Including investment allows us to explore the interaction of shareholder-creditor conflicts over investment and leverage choices.

We adjust our model so that investment is efficient and leads to the same cash flow dynamics as in the baseline setting. But if shareholders have the option to cut investment, debt overhang will induce them to do so when leverage is high, as in Myers (1977). Relative to the case without investment options, anticipated agency costs lower the debt price and reduce the rate of debt issuance when the leverage is low. But when leverage is high, the option to cut investment delays default and ultimately raises the debt price and rate of issuance. In the end, the tax benefits of debt are dissipated by the combined costs of underinvestment and default, so that the share price is again equal to the no trade value. Hence, because agency costs effectively substitute for default costs, in our model the ex ante value of equity is *not* diminished by the introduction of debt overhang, in stark contrast to standard tradeoff models. On the other hand, our results imply that tax subsidies intended to lower the cost of debt and thereby boost investment may instead have the opposite result.

While these insights are general, for ease of illustration we consider a simple linear investment decision.⁴⁹ Specifically, given an investment decision $i_t \in [\mu_0, \mu]$, the firm's rate of earnings before interest and taxes (EBIT), Y_t , evolves according to

$$dY_t = i_t Y_t dt + \sigma Y_t dZ_t.$$

Hence, when $i_t = \mu$, the firm invests optimally and grows at rate μ as before. But shareholders now have the option to cut investment and choose $i_t < \mu$. If they cut investment, the firm's free cash flow between $(t, t + dt)$ increases, and is given by

$$(1 - \bar{\pi}) Y_t dt + \kappa(\mu - i_t) Y_t dt,$$

where the parameter $\kappa > 0$ reflects the after-tax cost of investment (i.e., investing an extra $\$ \kappa$ today generates a permanent increase to Y_t of $\$1$). We assume the investment cost $\kappa < \phi = \frac{1 - \bar{\pi}}{r - \mu}$, so it is always positive NPV for an unlevered firm to invest. (The decision not to invest can also be interpreted as a decision to liquidate some existing capital and sacrifice growth.)

Our model with investment thus matches the setting in Section II except for the fact that shareholders now have the option to cut investment. We consider an MPE with the same state variable $y_t = Y_t / F_t$. As before, shareholders will default when y drops to an endogenous default threshold y_b^{inv} . In addition, there will exist an endogenous investment threshold y_i^{inv} such that if $y \geq y_i^{inv}$, leverage is sufficiently low so that shareholders will invest efficiently (and cash flows will evolve as in the baseline case). The new feature is that now, in the "distressed" region $y \in (y_b^{inv}, y_i^{inv})$, debt overhang is severe enough so that shareholders do not find it worthwhile to invest, but are not yet willing to default.

We solve this extension in closed form in Appendix VI.D, where we show that the no trade value remains strictly convex and thus can be used to characterize the smooth equilibrium. We demonstrate the interaction between investment and debt issuance in Figure 6 by comparing the case with endogenous investment (black dotted line) to the baseline setting in which investment is

⁴⁹ See the NBER working paper version <https://www.nber.org/papers/w22799> for a model with continuous investment and convex adjustment costs.

always fixed at first best (blue solid line). We plot the equity value v^{inv} , debt price p^{inv} , enterprise value $v^{inv} + p^{inv}$, and debt issuance rate in Panels A–D, respectively. The dashed vertical lines show the default boundaries for the two settings, whereas the solid vertical line shows the investment boundary when investment is endogenous.

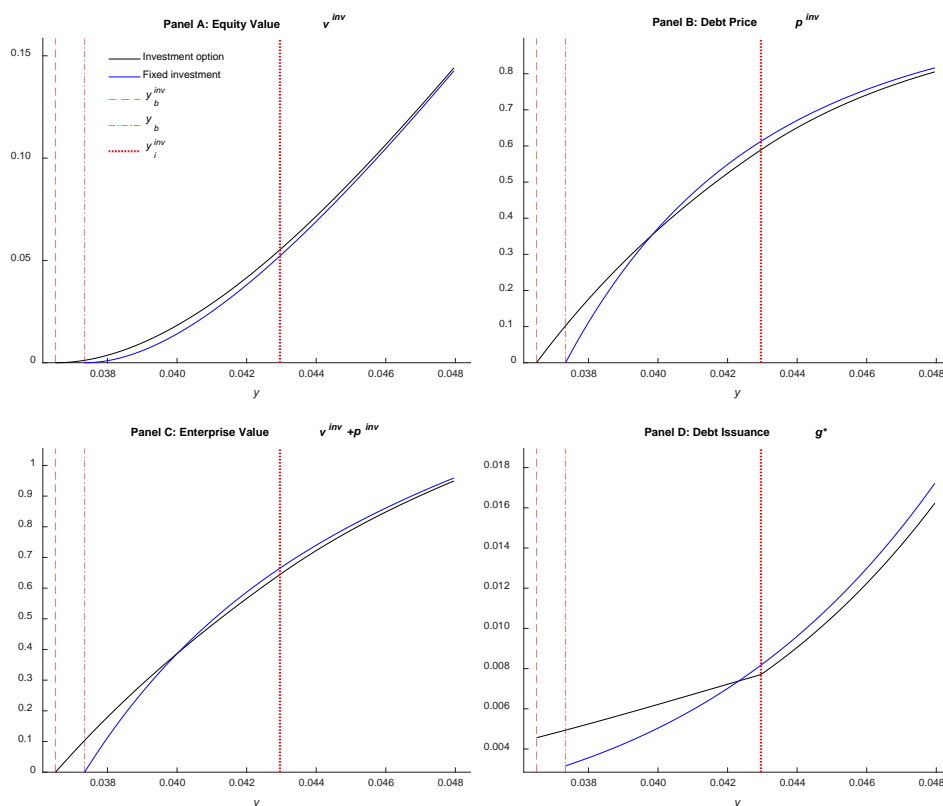

Figure 6 Endogenous Investment and Debt Issuance Policies.

The comparison between the extension with investment options and the baseline model: equity value v (Panel A), debt price p (Panel B), enterprise value $v + p$ (Panel C), and debt issuance policies g^* (Panel D). In the extension with investment options, the firm invests when $y \geq y_i^{inv}$, does not invest when $y \in (y_b^{inv}, y_i^{inv})$, and defaults when y hits y_b^{inv} . In the baseline model, the firm defaults earlier i.e. $y_b > y_b^{inv}$. Parameters are $r = c(1 - \bar{\pi}) = 5\%$,

$$\sigma = 10\%, \mu = 2\%, \xi = 0.01, \kappa = 22, \text{ and } \mu_0 = 0.$$

Compared to the baseline case, the option to cut investment and raise the firm's current free cash flow increases the value of equity and lowers the default boundary ($v^{inv} > v$ and $y_b^{inv} < y_b$) as shown in Panel A. In contrast, the option to cut investment lowers the debt price and enterprise

value when leverage is low, as creditors anticipate the cost of future underinvestment, but raises them when leverage is high, by delaying default, as shown in Panels B and C.

We plot debt issuance policies in both cases in Panel D. In the investment region $y \geq y_i^{inv}$, shareholders invest in both cases, but issue debt more slowly when there is the option to cut investment in the future. This slower debt issuance is a consequence of the greater sensitivity of the debt price to leverage increases when creditors anticipate that debt overhang will distort future investment. In the “distressed” region $y \in (y_b^{inv}, y_i^{inv})$, because shareholders can cut investment to boost the firm’s current cash flow, the issuance rate declines more slowly as y falls; ultimately, close to default, the debt issuance speed without investment exceeds the baseline case. We summarize the key results below:

PROPOSITION XI (UNDERINVESTMENT). *While the unlevered equity value is unchanged, for a given y the option to cut investment (or liquidate assets) inefficiently results in a higher equity value than in the case with fixed investment. Shareholders cut investment when y falls below $y_i^{inv} > y_b$, and default is delayed to $y_b^{inv} < y_b$. When $y \geq y_i^{inv}$, the firm invests optimally, and the value of equity satisfies*

$$v^I(y) = \phi y - \rho - \Lambda_I \left(\frac{y}{y_b} \right)^{-\gamma} (\phi y_b - \rho), \quad (46)$$

with $\Lambda_I > 1$. In this region, the rate of debt issuance is proportionally lower, and the credit spread is higher, than in the fixed investment case.

Proof: See the [Appendix](#). The intuition is as follows. First, we establish that for an arbitrary investment technology, the no trade value function remains convex, so that the characterization of the smooth equilibrium in Section I can be applied. Given a linear investment cost, the investment decision is “bang-bang” so that $i_t \in \{\mu_0, \mu\}$. When y_t is large, $v^I'(y) \approx \phi > \kappa$ and investment is efficient ($i_t = \mu$). When y_t falls, shareholders will cut investment ($i_t = \mu_0$) whenever debt overhang becomes severe enough that $v^I'(y_t) \leq \kappa$, which occurs at the threshold defined by $v^I'(y_i^{inv}) \equiv \kappa$. Recall that with zero recovery, $v^I(y_b) = 0$, so the option to cut investment is strictly profitable prior to default, hence $y_b^{inv} < y_b$. We can solve in closed form for the value function v^I

in the investment region as in Section II, with the optimal boundary y_i^{inv} determined by the usual smooth-pasting condition. The decision to cut investment is similar to a restructuring decision (as in Section II.D), with the parameters (α, β) determined endogenously from the value function v^M in the no investment region. Because the value of equity in such a “restructuring” is positive, it will be exercised earlier than when shareholders only had the option to default and receive zero; thus, $y_i^{inv} > y_b$. We show in the appendix that, as with our analysis in Section II.D, this disinvestment/restructuring option also implies $\Lambda_I > 1$. ■

In conclusion, we have shown that when shareholders cannot commit to a leverage policy, additional shareholder-creditor conflicts over investment policy have no incremental impact on the firm’s initial unlevered value. Instead, the anticipation of investment distortions widens initial credit spreads and slows the initial rate of debt issuance. Ultimately, the cost of the resulting investment distortions substitutes for default costs in fully offsetting the funding cost advantages of debt.

V. Conclusions

When the firm cannot commit ex ante to future leverage choices, shareholders will adjust the level of debt to maximize the firm’s current share price. We develop a general methodology to solve for equilibrium debt dynamics in this setting, including endogenous investment. When earnings evolve as geometric Brownian motion (including possible upward jumps), we show the uniqueness of our Markov perfect equilibrium, and explicitly solve for the firm’s debt as a slowly adjusting weighted average of past earnings. The endogenous rate of debt issuance decreases with debt maturity and volatility. The firm slows down its rate of debt issuance as it approaches default, so that the firm’s equilibrium leverage is ultimately mean-reverting.

Because creditors expect the firm to issue new debt in the future, credit spreads are wider in our model than in standard models with fixed debt and remain wide even when leverage is close to zero. Lower debt prices dissipate the tax shield benefits of leverage, so that the equity value is identical to the case without no future debt issuance. This inability to capture tax benefits of leverage may provide a possible resolution for the zero-leverage puzzle (Strebulaev and Yang,

2013), as the potential tax benefit from leverage is offset by the high credit spread even for initial debt.

Finally, although shortening the maturity of debt raises the average level of leverage as well as its speed of adjustment, the increase in expected tax benefits is again offset by an increase in investment distortions and default costs. As a result, even “instantaneous” debt does not resolve the commitment problem, and shareholders have no incentive to adjust the firm’s debt maturity structure. Moreover, because debt adjusts gradually, similar firms may have very different leverage given their exposure to past shocks. These observations offer a potential explanation for findings such as those by Lemmon, Roberts, and Zender (2008) that much of the cross-sectional variation in firms’ capital structures is persistent and largely unexplained by firm characteristics.

There are many further extensions of our model worth considering. DeMarzo (2019) allows for a different funding costs across equity and debt markets, perhaps due to different investor level taxes, or a “moneyness” premium associated with debt. DeMarzo, He, and Toure (2019) consider risk-averse creditors in the context of sovereign debt. As long as debt has a net funding advantage, all of the key results in our model continue to apply. The same holds true if we allow for proportional transactions costs associated with debt issuance (which can be interpreted as an additional wedge in the cost of capital across markets).

We have focused on Markov perfect equilibria in our analysis, in which debt pricing depends only on firm fundamentals. As in the folk theorem literature, if we relax this constraint, additional equilibria can be supported using “grim trigger” punishments in response to any deviation. Indeed, because our equilibrium produces the lowest possible equilibrium payoff for shareholders (Markov or not), *all* non-MPE equilibria can be supported by using our equilibrium off the equilibrium path. (See, for example, Benzoni et al. (2020) and Malenko and Tsoy (2020) who use our results to support non-Markov strategies in which the firm is “punished” for exceeding a target leverage ratio by reverting to our MPE.)

Naturally, we expect that firms will try to reduce the agency costs resulting from the leverage ratchet effect and capture some of the funding advantages of debt by using alternative commitment mechanisms such as collateral or covenants that restrict future debt issuance. Our results here imply that commitments to a leverage policy are more important to enhancing firm value than commitments regarding investment policy. DeMarzo (2019) discusses alternatives and

demonstrates that collateral allows the firm to capture the funding advantages of debt because it can be exclusively promised to a single creditor. Other important commitment mechanisms in practice include regulations, restrictions on the tax-deductibility of leverage by corporations, and trading frictions (for example, Benzoni et al. (2020) argue that fixed costs of debt issuance can act as a commitment mechanism allowing the firm to capture tax benefits of debt). Finally, equity market imperfections may prompt the firm to actively manage its internal liquidity (cash) position (as in Hennessy and Whited, 2005; Bolton, Chen, and Wang (2014) and Bolton, Wang, Yang (2020)). We leave for future work an exploration of the leverage dynamics that arise from the interaction of these additional forces with the leverage ratchet effects explored here.

VI. Appendix

A. Remaining Proofs from the Main Text

PROOF OF PROPOSITION VII. Note that the HJB equation (34) has the linear solution

$$\bar{v}(y) = \phi y - \rho. \quad (47)$$

The homogenous delayed differential equation

$$(r + \xi + \lambda)f(y) = (\hat{\mu} + \xi)yf'(y) + \frac{1}{2}\sigma^2 y^2 f''(y) + \lambda f(\theta y)$$

has solutions of the form $y^{-\hat{\gamma}}$ where $\hat{\gamma}$ solves the characteristic equation (35). In (35), because W is convex, $W(\infty) = W(-\infty) = \infty$, $W(0) < -r - \xi < 0$, and $W(-1) = \hat{\mu} - r < 0$; W has a unique positive real root (as well a unique negative real root $\hat{\eta} < -1$ that can be ruled out by the upper boundary condition). The remainder of the analysis follows exactly as in Section II.A. (See also Section B for an alternative proof in terms of $f = F/Y$). For the comparative statics, note by convexity and the fact that γ is the largest root, $W'(\gamma) > 0$. Hence, for a given parameter x , $\text{sign } \frac{\partial}{\partial x} \gamma = -\text{sign } \frac{\partial}{\partial x} W(\gamma)$, where

$$W(\gamma) = \lambda\theta^{-\gamma} + \frac{1}{2}\sigma^2\gamma^2 - \left(\mu - \lambda(\theta - 1) + \xi - \frac{1}{2}\sigma^2\right)\gamma - (r + \xi + \lambda) = 0.$$

So, for example, because $\theta > 1$ and $\gamma > 0$,

$$\frac{\partial}{\partial \theta} W(\gamma) = -\gamma\lambda\theta^{-(1+\gamma)} + \lambda\theta\gamma > 0,$$

we have that γ is strictly decreasing in θ . ■

PROOF OF PROPOSITION VIII. As in the proof of **PROPOSITION IV**, the equity value function given no trade is given by

$$\begin{aligned} v^J(y) &= \max_{\hat{y}_b} \phi y - \rho + \left(\frac{y}{\hat{y}_b}\right)^{-\gamma} \left(v^B(\hat{y}_b) - (\phi\hat{y}_b - \rho)\right) \\ &= \max_{j, \hat{y}_b} \phi y - \rho + \left(\frac{y}{\hat{y}_b}\right)^{-\gamma} \left((\alpha_j \phi \hat{y}_b - \beta_j \rho) - (\phi \hat{y}_b - \rho)\right) \\ &= \phi y - \rho - y^{-\gamma} \left[\min_{j, \hat{y}_b} \hat{y}_b^\gamma \left((1 - \alpha_j) \phi \hat{y}_b - (1 - \beta_j) \rho\right) \right]. \end{aligned}$$

From the first-order condition for \hat{y}_b ,

$$\hat{y}_b = \frac{(1-\beta_j)\rho\gamma}{(1-\alpha_j)\phi(1+\gamma)} = \frac{1-\beta_j}{1-\alpha_j} y_b.$$

Hence,

$$\begin{aligned} v^j(y) &= \phi y - \rho - y^{-\gamma} \left[\min_j \hat{y}_b^\gamma (1-\beta_j) (\phi y_b - \rho) \right] \\ &= \phi y - \rho - \left(\frac{y}{y_b} \right)^{-\gamma} (\phi y_b - \rho) \left[\max_j \left(\frac{1-\beta_j}{1-\alpha_j} \right)^\gamma (1-\beta_j) \right] \\ &= \phi y - \rho - \Lambda_j \left(\frac{y}{y_b} \right)^{-\gamma} (\phi y_b - \rho). \end{aligned}$$

The remaining results follow from **PROPOSITION III** as in Section II.A. ■

PROOF OF PROPOSITION X: The result follows from a straightforward extension of the methodology in Section I. Let $F = (F_o, F_n)$ be a vector showing the quantity of old and new debt, respectively. Let $c = (c_o, c_n)$ and $\xi = (\xi_o, \xi_n)$ be the corresponding coupon and amortization rates. Given (Y, F) the firm generates cash at rate $u(Y, F) = Y - \pi(Y - c \cdot F) - (c + \xi) \cdot F$. Let $p^n(Y, F)$ be the price of the new debt and $V(Y, F)$ be the value of equity. Then the equity value function satisfies the HJB,

$$\underbrace{rV}_{\text{required return}} = \max_G \left[u(Y, F) + \underbrace{Gp^n}_{\text{new debt issuance}} + \underbrace{(G - \xi_n F_n)V_{F_n} - \xi_o F_o V_{F_o}}_{\text{evolution of } dF} + \underbrace{\mu(Y)V_Y + \frac{1}{2}\sigma(Y)^2 V_{YY}}_{\text{evolution of } dY} \right].$$

As before, if a smooth issuance policy is optimal it must be that $p^n = V_{F_n}$. Thus the HJB becomes

$$rV = u(Y, F) - \xi_n F_n V_{F_n} - \xi_o F_o V_{F_o} + \mu(Y)V_Y + \frac{1}{2}\sigma(Y)^2 V_{YY},$$

equivalent to the case with no future trade. Note that before the firm issues new debt, $F_n = 0$, and hence the value of equity $V(Y, (F_o, 0)) = V(Y, F_o)$ is independent of coupon rate or maturity

(c_n, ξ_n) of the new debt. Finally, following the same approach as in Section I, we can solve for the optimal G^* as before:

$$G^* = \frac{\frac{\partial}{\partial F_n} u(Y, F) + c_n + \xi_n}{-P_{F_n}^n} = \frac{\pi' c_n}{-P_{F_n}^n}.$$

Thus, the smooth equilibrium will exist under the same conditions as before (differentiability and strict convexity with respect to the debt face value). ■

B. Solving the Model in Terms of f

In some cases it is more convenient to solve the model in terms of the state variable $f = F/Y = 1/y$, especially when considering an initially unlevered firm ($F = 0$). Let $\hat{v}(f)$ be the value function in terms of f ; that is, $\hat{v}(f) = V(1, f) = V(Y, F)/Y$. Note the given a jump, the value becomes $V(\theta Y, F)/Y = \theta \hat{v}(f/\theta)$. Hence, the HJB equation for $\hat{v}(f)$ given no trade is

$$(r - \hat{\mu})\hat{v}(f) = (1 - \bar{\pi})(1 - cf) - \xi f - (\hat{\mu} + \xi)f\hat{v}'(f) + \frac{1}{2}\sigma^2 f^2 \hat{v}''(f) + \lambda \left(\theta \hat{v}\left(\frac{f}{\theta}\right) - \hat{v}(f) \right). \quad (48)$$

Recall we have defined $\mu = \hat{\mu} + \lambda(\theta - 1) < r$. According to Liu (2018) Theorem 2.2, the general solution of (48) is of the form

$$\hat{v}(f) = \phi - \rho f + A_1 f^{\hat{\gamma}} + A_2 f^{-\hat{\eta}}, \quad (49)$$

with A_1 and A_2 as coefficients to be determined. The two power functions of $f^{\hat{\gamma}}$ and $f^{-\hat{\eta}}$ are derived as follows. The characteristic equation of the homogeneous part is

$$\hat{W}(x) = \lambda \theta^{1-x} + 0.5\sigma^2 x^2 - (\hat{\mu} + \xi + 0.5\sigma^2)x - (r - \hat{\mu} + \lambda) = 0.$$

Because $\hat{W}''(x) = \lambda \theta^{1-x} (\ln \theta)^2 + \sigma^2 > 0$, $\hat{W}(x)$ is convex. In addition, because $\hat{W}(-\infty) = \hat{W}(+\infty) = \infty$ and both $\hat{W}(0) = -(r - \hat{\mu}) < 0$ and $\hat{W}(1) = -\xi - r < 0$, we have two real roots $\hat{\gamma} > 1$ and $-\hat{\eta} < 0$ for the equation $\hat{W}(x) = 0$. It is easy to check that $\hat{\gamma} = 1 + \gamma$ from (35).

Because $\hat{v}(0)$ is bounded we must have $A_2 = 0$ and $\hat{v}(0) = \phi$. Then, A_1 is determined from the boundary condition $\hat{v}(f_b) = \hat{v}'(f_b) = 0$, which implies

$$\hat{v}(f) = \phi - \rho f - \left(\frac{f}{f_b} \right)^{\hat{\gamma}} (\phi - \rho f_b) \quad \text{with} \quad f_b = \frac{\hat{\gamma}}{\hat{\gamma} - 1} \frac{\phi}{\rho}.$$

It is straightforward to check that $f_b = 1 / y_b$ and $\hat{v}(f) = v(y) / y$.

C. Equilibrium Uniqueness

We prove that the smooth equilibrium constructed in Section II is the unique equilibrium in the class of Markov perfect equilibria with the uni-dimensional state variable being $y = Y / F$. There are five steps in our proof strategy.

- 1) *The equity value $v(y)$ is weakly convex, continuously differentiable C^1 , and debt price function $p(y)$ is continuous and increasing.*⁵⁰

These regularity conditions are satisfied by the equity value and debt price in any equilibrium; most of them are straightforward implications of Proposition 1, but utilize the strength of having only a single state variable y to rule out discontinuities in the debt price.

- 2) *There will be no buybacks in any Markov equilibria with Markov state (Y, F) .*

We show that by deferring any planned buybacks, the firm will benefit from tax shields and its default option. This step is crucial, as it will allow us to focus on monotone issuance policies. It also does not depend on the assumption that the equilibrium is Markov in y .

- 3) *The state variable y_t is a smooth process, plus some singular non-increasing process.*

Following on step 2, we use the Lebesgue decomposition which says a monotone process can be decomposed to an absolutely continuous part and a singular part.

- 4) *There are no gains from trade for an initially unlevered firm.*

Here we show that in any equilibrium, $V(Y, 0) = \phi Y$, and thus there are no gains from trade for an initially unlevered firm.

- 5) *The equilibrium issuance policy is absolutely continuous.*

⁵⁰ Recall that we use the term “increasing” in the weak sense throughout the paper (see footnote 11).

Having shown that the equilibrium payoff for an unlevered firm is unchanged, the last step is to rule out the possibility of singular strategies in equilibrium.

Together, these steps verify that our constructed equilibrium—in which the debt issuance policy is absolute continuous in time (i.e., smooth)—is the unique MPE in y .

C.1 Convexity and Differentiability of the Equity Value

We first prove some regularity properties for the scaled equity value function $v(y) = V(Y, F) / F$. Denote y_b as the default policy in any equilibrium, which, with a slight abuse of notation, could differ from no trade default boundary y_b^0 (in our constructed equilibrium, they coincide as in equation (26)).

Lemma A.1. *We have the following properties.*

- a) *There exists a default boundary y_b so that shareholders continue whenever $y > y_b$ with $y_b < y_b^0$;*
- b) *$v(y)$ is increasing, weakly convex, continuously differentiable C^1 , and the debt price function $p(y) = yv'(y) - v(y)$ is continuous and increasing over the region $y \in [y_b, \infty)$;*
- c) *When v is linear in some interval, $p(y)$ is a constant and positive in that interval.*

Proof: To start, because $v(y) \geq v^0(y) > 0$ for $y \geq y_b^0$, we know that it is optimal to continue for $y \geq y_b^0$, and implying that $y_b < y_b^0$. The optimality of the proposed threshold strategy follows from the monotonicity and convexity established in b).

For b), the monotonicity of $v(y)$ comes from $V(Y, F)$ being decreasing in F shown in Proposition 1. And,

$$V(Y, F) \geq V(Y, \hat{F}) + (\hat{F} - F)p(Y, \hat{F}) \Rightarrow \frac{v(y)}{y} \geq \frac{v(\hat{y})}{\hat{y}} + \left(\frac{1}{\hat{y}} - \frac{1}{y} \right) p(\hat{y})$$

Define $q(y) \equiv \frac{v(y) + p(y)}{y} > 0$; then the above inequality is equivalent to

$$v(y) \geq v(\hat{y}) + (y - \hat{y})q(\hat{y}),$$

implying v is weakly convex in y and q is a subgradient.

Next, the value function must be smooth (continuously differentiable) in Y ; otherwise at a kink there would be an infinite expected rate of gain given the Brownian motion in Y (note, shareholders have the option to issue no debt and hence reap this infinite gain, if it exists). As a result, v is C^1 in y , which implies that $v' = q$, and $p = yv' - v$ follows. Since Proposition 1 shows that $p(Y, F)$ is decreasing in F , it follows that in our MPE $p(y)$ is increasing in y .

For c), in any interval (y_1, y_2) with $y_2 > y_1 \geq y_b$, if $v(y) = v(y_1) + v'(y_1)(y - y_1)$ for $y \in (y_1, y_2)$, then in this interval the debt price $p(y) = yv'(y) - v(y)$ must be equal to $yv'(y_1) - v(y_1) - v'(y_1)(y - y_1) = y_1v'(y_1) - v(y_1)$, a constant independent of y . Finally, $p(\cdot)$ is positive because in equilibrium default occurs immediately if and only if $p = 0$. ■

C.2 No Buybacks

As mentioned in **PROPOSITION I**, the result of no debt buyback generally holds for any Markov equilibrium, with the Markov states being exogenous cash flow Y and endogenous debt face value F . Hence this constitutes the formal proof for the first result in **PROPOSITION I**.

The key idea behind the proof is as follows. Given a potential equilibrium debt issuance policy with buybacks, we show that equity holders can strictly improve their value by following an alternative strategy without buybacks taking the price function $p(Y, F)$ as given. For example, consider a strategy in which the firm buys back \$1 (face value) of debt at date t and then issues \$3 of debt at date $t+1$. Shareholders would strictly gain by postponing the buyback at t and issuing only \$2 at $t+1$ —the final debt level and debt price (by the Markov assumption) are the same, but the firm earns the incremental tax shield from \$1 of debt between date t and $t+1$. In addition, shareholders retain the option to default on the additional \$1 of debt, further enhancing their payoff.

Formally, suppose there exists an equilibrium starting from $F_0 \geq 0$ and with $dF_t = -\xi F_t dt + d\Gamma_t$, or equivalently, $F_t = e^{-\xi t} F_0 + \int_0^t e^{\xi(s-t)} d\Gamma_s$. The associated bond valuation equation implies that the bond price $p_t = p(Y_t, F_t)$ satisfies

$$(r + \xi) p_t dt = (c + \xi) dt + E_t[dp_t] \Leftrightarrow E_t[rp_t dt - dp_t] = c dt + \xi(1 - p_t) dt. \quad (50)$$

Consider an alternative policy without buybacks defined by

$$\hat{F}_t \equiv \sup_{s \leq t} \left\{ e^{-\xi(t-s)} F_s \right\} \geq F_t;$$

because $d\hat{\Gamma}_t = d\hat{F}_t + \xi \hat{F}_t dt$, one can show that

$$d\hat{\Gamma}_t = \max\left(0, F_t - \hat{F}_{t-}\right) = \max\left(0, d\Gamma_t + \int_0^{t-} e^{\xi(s-t)} (d\Gamma_s - d\hat{\Gamma}_s)\right) \geq 0, \quad (51)$$

which features no buybacks. Intuitively, this policy postpones any buybacks, issuing debt only as needed to prevent the new debt level \hat{F}_t from ever falling below the original debt level F_t . We will show that if the original policy has debt buybacks, then shareholders would gain by deviating to this new policy, and so the policy with buybacks cannot be an equilibrium.

Shareholders take the debt price function $p(Y, F)$ as given, and so anticipate a debt price of $\hat{p}_t \equiv p(Y_t, \hat{F}_t)$ under the new debt policy. Let $d\Gamma_t^\Delta \equiv d\hat{\Gamma}_t - d\Gamma_t$ be the deviation of the issuance policy, and $F_t^\Delta \equiv \hat{F}_t - F_t$ be the deviation of the debt path, which equals the cumulative deviation of debt issuances:

$$F_t^\Delta = \int_0^t e^{\xi(s-t)} d\hat{\Gamma}_s - \int_0^t e^{\xi(s-t)} d\Gamma_s = \int_0^t e^{\xi(s-t)} d\Gamma_s^\Delta. \quad (52)$$

As a result, we have

$$dF_t^\Delta = d\Gamma_t^\Delta - \xi F_t^\Delta dt \Leftrightarrow d\Gamma_t^\Delta = dF_t^\Delta + \xi F_t^\Delta dt. \quad (53)$$

Note that if shareholders deviate to \hat{F} , they may also reoptimize their default policy accordingly. Doing so can only further improve the payoff from deviating. Hence, to show the deviation is profitable, it is sufficient to show that the non-negative issuance policy $d\hat{\Gamma}$ dominates

$d\Gamma$, given the default timing τ_b , as a function of cash-flow history $\{Y_t\}$, under the original issuance policy. We establish this below.

Lemma A.2. *We have*

$$F_t^\Delta \geq 0 \text{ for } \forall t \in [0, \tau_b], \text{ with } F_0^\Delta = 0, \text{ and} \quad (54)$$

$$\hat{p}_t d\hat{\Gamma}_t - p_t d\Gamma_t = p_t (d\hat{\Gamma}_t - d\Gamma_t) = p_t d\Gamma_t^\Delta. \quad (55)$$

Proof: The claim in (54) is obvious. Because issuance only occurs under the new policy in order to keep \hat{F}_t from falling below F_t , we have $d\hat{\Gamma}_t > 0 \Rightarrow \hat{F}_t = F_t \Rightarrow \hat{p}_t = p_t$, where the final implication follows from the Markov property that the debt price depends on Y and F only (and not their history). Although the debt price may differ when $d\hat{\Gamma}_t = 0$, the total issuance proceeds are not affected, and hence $\hat{p}_t d\hat{\Gamma}_t = p_t d\hat{\Gamma}_t$, proving (55). ■

Now we are ready to show the gain from postponing buybacks (fixing the timing of default). Define

$$\pi_t^\Delta \equiv \pi(Y_t - c\hat{F}_t) - \pi(Y_t - cF_t) \leq 0,$$

and note that, because π is strictly decreasing and $\hat{F}_t \geq F_t$, π_t^Δ is strictly negative whenever $\hat{F}_t \neq F_t$. The change in the value of equity can then be expressed as

$$\begin{aligned} V_0^\Delta = \hat{V}_0 - V_0 &= E \left\{ \int_0^{\tau_b} e^{-rt} \left((c + \xi)(F_t - \hat{F}_t) + \pi(Y_t - cF_t) - \pi(Y_t - c\hat{F}_t) \right) dt + e^{-r\tau_b} \left(\hat{p}_{\tau_b} d\hat{\Gamma}_{\tau_b} - p_{\tau_b} d\Gamma_{\tau_b} \right) \right\} \\ &\stackrel{\text{Eq (54)}}{=} E \int_0^{\tau_b} \left[e^{-rt} p_t d\Gamma_t^\Delta - e^{-rt} \left((c + \xi) F_t^\Delta + \pi_t^\Delta \right) dt \right] \\ &\stackrel{\text{Eq (52)}}{=} E \int_0^{\tau_b} \left[e^{-rt} p_t \left[dF_t^\Delta + \xi F_t^\Delta dt \right] - e^{-rt} \left((c + \xi) F_t^\Delta + \pi_t^\Delta \right) dt \right] \\ &= E \int_0^{\tau_b} e^{-rt} p_t dF_t^\Delta - E \int_0^{\tau_b} e^{-rt} (c + \xi(1 - p_t)) F_t^\Delta dt - E \int_0^{\tau_b} e^{-rt} \pi_t^\Delta dt. \end{aligned}$$

Integration by parts for the first term $E \int_0^{\tau_b} e^{-rt} p_t dF_t^\Delta$ gives

$$\begin{aligned}
E \left\{ \int_0^{\tau_b} e^{-rt} p_t dF_t^\Delta \right\} &= E \left\{ e^{-r\tau_b} p_{\tau_b} F_{\tau_b}^\Delta - p_0 F_0^\Delta - \int_0^{\tau_b} F_t^\Delta \cdot e^{-rt} [E_t(dp_t) - rp_t dt] \right\} \\
&\stackrel{\text{Eq. (49)}}{=} E \left\{ e^{-r\tau_b} p_{\tau_b} F_{\tau_b}^\Delta - p_0 F_0^\Delta + \int_0^{\tau_b} F_t^\Delta \cdot e^{-rt} (c + \xi(1 - p_t)) dt \right\}.
\end{aligned}$$

Plugging in this result back into our calculation of V_0^Δ , and using (54) together with the fact that $p_{\tau_b} = 0$ under the original policy, we have

$$\begin{aligned}
V_0^\Delta &= E \left\{ e^{-r\tau_b} \underbrace{p_{\tau_b}}_{=0} F_{\tau_b}^\Delta - p_0 \underbrace{F_0^\Delta}_{=0} - E \int_0^{\tau_b} e^{-rt} \pi_t^\Delta dt \right\} \\
&= -E \int_0^{\tau_b} e^{-rt} \pi_t^\Delta dt \geq 0,
\end{aligned}$$

where the inequality is strict unless $\hat{F}_t = F_t$ and the original policy had no buybacks. Otherwise, shareholders strictly gain by capturing the debt tax shield on any deferred buybacks. This completes the proof that there are no buybacks in equilibrium.

C.3 Smooth versus Singular Issuance

The important no buyback result implies that the equilibrium issuance policy Γ_t must be non-decreasing over time. By Lebesgue's decomposition for monotonic functions (cf. Proposition 5.4.5, Bogachev, 2013), we can decompose Γ_t into a smooth and singular process

$$\Gamma_t = \Gamma_t^{\text{a.c.}} + \underbrace{\Gamma_t^{\text{c.s.}} + \Gamma_t^{\text{jump}}}_{\Gamma_t^{\text{singular}}} \tag{56}$$

Here, $\Gamma_t^{\text{a.c.}}$ is an absolutely continuous process, so that there exists some positive process G_t so that $d\Gamma_t^{\text{a.c.}} = G_t dt$. The component $\Gamma_t^{\text{c.s.}}$ captures continuous but singular increases that occur at isolated points on the state space (e.g., a “devil’s staircase”); and $d\Gamma_t^{\text{jump}}$ captures discrete jumps. We aim to rule out both $\Gamma_t^{\text{c.s.}}$ and Γ_t^{jump} , which we call $\Gamma_t^{\text{singular}}$, in any equilibrium, and thereby establish the desired result.

Under our assumption that Y_t evolves according to a geometric Brownian motion and that the equilibrium is Markov perfect in y , the decomposition in (56) implies that we can write

$$dy_t = d\left(\frac{Y_t}{F_t}\right) = y_t(\hat{\mu} - \xi + g(y_t)dt) + y_t\sigma dZ_t + (\theta - 1)y_{t-}dN_t - dL_t^{\text{singular}}$$

for some singular increasing process $L_t^{\text{singular}} = L_t^{\text{c.s.}} + L_t^{\text{jump}} > 0$. Here $L_t^{\text{c.s.}}$ (L_t^{jump}) occurs if and only if $\Gamma_t^{\text{c.s.}}$ (Γ_t^{jump}) occurs.

We now show that the existence of a non-zero singular component to the optimal strategy implies the existence of $\hat{y} > y_b$ such that $v''(\hat{y}) = 0$. There are two cases to consider.

First, consider L_t^{jump} . By **LEMMA “CONTINUOUS ADJUSTMENT”** in Section I.B, the optimal issuance strategy can jump only in an interval for which $V(Y, F)$ is linear in F and therefore, by **PROPOSITION I**, the debt price is constant. In our homogenous setting, $y^2v''(y) = FV_{FF}$, and so a jump can only occur in an interval for which $v(y)$ is linear. Let \hat{y} be the lower bound of this linear segment. Because it is not optimal to jump to default, we can assume $\hat{y} > y_b$. Note that $p'_+(\hat{y}) = 0$, and therefore $p'_-(\hat{y}) = 0$ as otherwise the debt price would have an infinite expected loss rate at \hat{y} , violating no arbitrage. Thus, $p'(\hat{y}) = v''(\hat{y}) = 0$.

Second, consider an isolated singular point \hat{y} for which $L_t^{\text{c.s.}} \geq 0$ (note $L_t^{\text{c.s.}} > 0 \Leftrightarrow \Gamma_t^{\text{c.s.}} > 0$ and $L_t^{\text{c.s.}} = 0 \Leftrightarrow \Gamma_t^{\text{c.s.}} = 0$; see the discussion at the end of Step 3). Based on the study of “skew Brownian motion” in Harrison and Shepp (1981), if $l_{\hat{y}}^y(t)$ is the local time that the process $\{y_t\}$ spends at $y_t = \hat{y}$, then we have for some positive constant $\chi \in (0, 1]$,

$$L_t^{\text{c.s.}} = \chi \cdot l_{\hat{y}}^y(t). \quad (57)$$

The speed of change is proportional to local time (continuous in time but faster than dt , as it is not absolutely continuous in time). As a result, the excursions of the state variable are asymmetric, with probability $\frac{1}{2}(1 + \chi)$ to the left and with probability $\frac{1}{2}(1 - \chi)$ to the right. The no arbitrage condition for bond investors requires that the expected local gain at \hat{y} is zero, therefore

$$\frac{1}{2}(1 - \chi)p'_+(\hat{y}) = \frac{1}{2}(1 + \chi)p'_-(\hat{y}). \quad (58)$$

Because the singular point \hat{y} must be isolated, there is an open ball $B \equiv (\hat{y} - \varepsilon, \hat{y} + \varepsilon)$ so that $dL_t^{\text{singular}} = 0$ on $B \setminus \hat{y}$. Because v and v' are continuous, and since the HJB equation for v holds and is identical on the left-hand and right-hand sides of \hat{y} , we must have v'' continuous at \hat{y} , and therefore $p'_+(\hat{y}) = p'_-(\hat{y}) = v''(\hat{y}) = 0$.

C.4 No Gains from Trade

Next we prove that in any equilibrium an initially unlevered firm achieves no gains from trade and thus has value ϕY . Specifically,

$$\frac{V(Y, 0)}{Y} = \lim_{F \rightarrow 0} \frac{V(Y, F)}{Y} = \lim_{y \rightarrow \infty} \frac{v(y)}{y} = \lim_{y \rightarrow \infty} v'(y) = \phi. \quad (59)$$

We must consider three cases regarding the trading strategy for the unlevered firm: (i) trading is smooth in a neighborhood of $F = 0$, (ii) the firm immediately issues debt $F > 0$, or (iii) trading is singular in any neighborhood of $F = 0$.

Case (i): Trading is smooth in a neighborhood of $F = 0$.

In this case, we can use the fact that $V(Y, 0) = \hat{v}(0)Y$ and apply the results of Section B. Because trading is smooth, the HJB equation (48) applies in a neighborhood of $f = 0$ and has solution of the form (49). Because $V(Y, 0)$ is bounded, $A_2 = 0$, and therefore $\hat{v}(0) = \phi$.

Case (ii): The firm immediately issues debt $F > 0$.

For a jump to be optimal, there exists some largest \hat{y} such that $v(y)$ is linear for $y \geq \hat{y}$. Differentiating the HJB equation (34) and using linearity plus the fact that $v''(\hat{y}) = 0$ and therefore $v'''_-(\hat{y}) \leq 0$ from Step 3,

$$\begin{aligned} (r + \xi)v'(\hat{y}) &= 1 - \bar{\pi} + (\hat{\mu} + \xi) \left[\hat{y} \underbrace{v''_-(\hat{y})}_0 + v'(\hat{y}) \right] + \frac{1}{2} \sigma^2 \left[\hat{y}^2 \underbrace{v'''_-(\hat{y})}_{\leq 0} + 2\hat{y}v''_-(\hat{y}) \right] + \lambda \left(\underbrace{\theta v'(\theta \hat{y})}_{\theta v'(\hat{y})} - v'(\hat{y}) \right) \\ &\leq 1 - \bar{\pi} + (\hat{\mu} + \xi)v'(\hat{y}) + \lambda(\theta - 1)v'(\hat{y}) = 1 - \bar{\pi} + (\mu + \xi)v'(\hat{y}) \end{aligned}$$

Therefore,

$$v'(\hat{y}) \leq \frac{1-\bar{\pi}}{r-\mu} = \phi. \quad (60)$$

But because $V(Y, 0) \geq \phi Y$ since the firm always has the option not to trade, we must have $v'(y) = \phi$ for $y \geq \hat{y}$.

Case (iii): Trading is singular in any neighborhood of $F = 0$.

In this case, using the results of Step 3, there exists an increasing sequence of points $\{\hat{y}_n \rightarrow \infty\}$ such that $v''(\hat{y}_n) = 0$ and $v'''(\hat{y}) \leq 0$. Differentiating the HJB equation (34) as in Case (ii), but without assuming linearity in the jump region,

$$\begin{aligned} (r + \xi)v'(\hat{y}_i) &\leq 1 - \bar{\pi} + (\hat{\mu} + \xi)v'(\hat{y}_i) + \lambda(\theta - 1)v'(\hat{y}_i) + \lambda\theta(v'(\theta\hat{y}_i) - v'(\hat{y}_i)) \\ &= 1 - \bar{\pi} + (\mu + \xi)v'(\hat{y}_i) + \lambda\theta(v'(\theta\hat{y}_i) - v'(\hat{y}_i)) \end{aligned}$$

Taking the limit as $\hat{y}_i \rightarrow \infty$, and because $\lim_{y \rightarrow \infty} v'(y)$ converges monotonically (from convexity and the fact that $V(Y, 0)$ is bounded in (59)), we get

$$\lim_{y \rightarrow \infty} v'(y) \leq \frac{1-\bar{\pi}}{r-\mu} = \phi.$$

Again, because the firm has the option not to trade, we must have $\lim_{y \rightarrow \infty} v'(y) = \phi$.

C.5 Smooth Issuance

Now that we have established there are no gains from trade, we complete the proof that the smooth equilibrium is the unique MPE by showing that the equilibrium trading strategy does not involve singularities.

We begin with a result that bounds the potential gain from a cash flow jump:

LEMMA A.3 (GAINS FROM CASH FLOW JUMPS). *For $\theta \geq 1$ and any two points y and y_1 so that $y_1 \geq y \geq y_b$, we have*

$$v(y) \geq v(\theta y) - v'(\theta y)(\theta - 1)y \geq v(\theta y) - \phi(\theta - 1)y \quad (61)$$

$$v(\theta y_1) \geq v(\theta y) + v'(\theta y)(y_1 - y) \geq v(\theta y) + \theta v'(y)(y_1 - y) \quad (62)$$

Proof: In both cases, the first inequality follows from convexity, and the second from the fact that v' is monotonically increasing and, from Step 4, bounded by ϕ . ■

Next, suppose there exist a singular component to the optimal trading strategy. From Step 3, there exists \hat{y} with $v''(\hat{y})=0$, and for which trading is smooth (and the HJB holds) in the neighborhood just below \hat{y} . Evaluating the HJB of $v(\cdot)$ at \hat{y} ,

$$\begin{aligned}
(r + \xi)v(\hat{y}) &= (1 - \bar{\pi})(\hat{y} - c) - \xi + (\hat{\mu} + \xi)\hat{y}v'(\hat{y}) + \frac{1}{2}\sigma^2\hat{y}^2v''(\hat{y}) + \lambda(v(\theta\hat{y}) - v(\hat{y})) \\
&= (1 - \bar{\pi})(\hat{y} - c) - \xi + (\hat{\mu} + \xi)\hat{y}v'(\hat{y}) + \lambda(v(\theta\hat{y}) - v(\hat{y})) \\
&\leq (1 - \bar{\pi})(\hat{y} - c) - \xi + (\hat{\mu} + \xi)\hat{y}\phi + (\hat{\mu} + \xi)\hat{y}(v'(\hat{y}) - \phi) + \lambda(\theta - 1)\phi\hat{y} \\
&= \underbrace{(1 - \bar{\pi})}_{(r - \mu)\phi}\hat{y} + \underbrace{\left(\hat{\mu} + \lambda(\theta - 1) + \xi\right)}_{\mu}\hat{y}\phi - (c(1 - \bar{\pi}) + \xi) + (\hat{\mu} + \xi)\hat{y}(v'(\hat{y}) - \phi) \\
&= (r + \xi)(\phi\hat{y} - \rho) + (\hat{\mu} + \xi)\hat{y}(v'(\hat{y}) - \phi)
\end{aligned}$$

where the inequality follows from (61). Now because any equilibrium must be at least as good as no trade, $v(y) \geq v^0(y) > \phi y - \rho$, and so the above implies

$$(\hat{\mu} + \xi)(v'(\hat{y}) - \phi) > 0. \quad (63)$$

Note from Step 4, $v'(y) \leq \phi$, and therefore (63) implies an immediate contradiction if $\hat{\mu} + \xi > 0$. We have not restricted the sign of $\hat{\mu} + \xi$, however, and so we argue next that at a singular point $v'(\hat{y}) \geq \phi$. Then, combined with Step 4, $v'(\hat{y}) = \phi$, and thus (63) cannot be satisfied.

There are three cases to consider.

Case (i): The firm immediately issues debt $F > 0$.

In this case, $v(y) = v(\hat{y}) + v'(\hat{y})(y - \hat{y})$ for $y > \hat{y}$. Then,

$$0 \leq v(y) - v^0(y) < v(y) - (\phi y - \rho) = (v'(\hat{y}) - \phi)y + (v(\hat{y}) - v'(\hat{y})\hat{y} - \rho).$$

Letting $y \rightarrow \infty$, the above implies $v'(\hat{y}) \geq \phi$.

Case (ii): Interior jump.

Suppose there is an interior interval $[\hat{y}, y_1]$ on which y is linear (and strictly convex at each end). Taking the difference between the HJB equations at \hat{y} and y_1 ,

$$\begin{aligned}(r + \xi)v(y_1) &= (1 - \bar{\pi})(y_1 - c) - \xi + (\hat{\mu} + \xi)y_1 v'(y_1) + \frac{1}{2}\sigma^2 y_1^2 v''_+(y_1) + \lambda(v(\theta y_1) - v(y_1)) \\ (r + \xi)v(\hat{y}) &= (1 - \bar{\pi})(\hat{y} - c) - \xi + (\hat{\mu} + \xi)\hat{y} v'(\hat{y}) + \frac{1}{2}\sigma^2 \hat{y}^2 v''_-(\hat{y}) + \lambda(v(\theta \hat{y}) - v(\hat{y}))\end{aligned}$$

and using the fact that $v(y_1) = v(\hat{y}) + v'(\hat{y})(y_1 - \hat{y})$ and $v''_+(y_1) \geq 0 = v''_-(\hat{y})$,

$$\begin{aligned}\left(r - \underbrace{\hat{\mu} + \lambda(\theta - 1)}_{\mu}\right)v'(\hat{y})(y_1 - \hat{y}) &\geq (1 - \bar{\pi})(y_1 - \hat{y}) + \lambda(v(\theta y_1) - v(\theta \hat{y})) - \theta v'(\hat{y})(y_1 - \hat{y}) \\ &\geq (1 - \bar{\pi})(y_1 - \hat{y})\end{aligned}$$

where the second inequality follows from (62). Dividing both sides by $(r - \mu)(y_1 - \hat{y})$ we have $v'(\hat{y}) \geq \phi$.

Case (iii): Isolated singular point.

From Step 3, we know that $v''(\hat{y}) = 0$. Since it is isolated, the HJB holds on both sides of \hat{y} . By taking the derivative of the HJB and looking at the *right*-hand side of \hat{y} , since $v''(y) \geq 0$ at $\hat{y}+$, we have $v''_+(\hat{y}) \geq 0$ and hence

$$\begin{aligned}(r + \xi)v'(\hat{y}) &= 1 - \bar{\pi} + (\hat{\mu} + \xi)\left[\underbrace{\hat{y} v''(\hat{y})}_{=0} + v'(\hat{y})\right] + \frac{1}{2}\sigma^2\left[\underbrace{\hat{y}^2 v''_+(\hat{y})}_{\geq 0} + 2\hat{y}\underbrace{v''(\hat{y})}_{=0}\right] + \lambda\left(\underbrace{\theta v'(\theta \hat{y})}_{\geq \theta v'(\hat{y}), \text{ as } \theta \geq 1} - v'(\hat{y})\right) \\ &\geq 1 - \bar{\pi} + \left(\underbrace{\hat{\mu} + \lambda(\theta - 1)}_{\mu} + \xi\right)v'(\hat{y})\end{aligned}$$

which implies that $v'(\hat{y}) \geq \phi$. This completes the proof of uniqueness. ■

D. Endogenous Investment

We begin with a general proof that with a constant marginal tax rate, the no trade value function is convex in F .

LEMMA A.4 (CONVEXITY OF NO TRADE VALUE FUNCTION WITH INVESTMENT). *Suppose the tax rate is constant and let \hat{Y}_t^i be any after-tax cash flow process given some investment policy $i_t = i(Y_t, F_t)$. Then the no trade value function is convex in F .*

Proof: Given initial debt levels (F_0, F_1) with maturity ξ , define

$$F_s^\alpha \equiv \alpha F_s^1 + (1-\alpha) F_s^0 = \alpha F_1 e^{-\xi s} + (1-\alpha) F_0 e^{-\xi s}.$$

Let $\hat{c} = c(1-\bar{\pi}) + \xi$ be the total after-tax debt burden per unit debt face value, and let \hat{Y}_t^i be the after-tax cash flow process given investment policy $i_t = i(Y, F)$ so that the firm generates $\hat{Y}_t^i dt$ over the period of $(t, t + dt)$. Then the no trade value function, given the optimal investment $i(Y, F)$ and default $\tau(Y, F)$ policies, satisfies

$$\begin{aligned} V(Y, \alpha F_1 + (1-\alpha) F_0) &= \max_{i, \tau} E \left[\int_0^\tau e^{-r(s-t)} (\hat{Y}_s^i - \hat{c} F_s^\alpha) ds \right] \\ &= \max_{i, \tau} E \left[\int_0^\tau e^{-r(s-t)} (\hat{Y}_s^i - \hat{c} [\alpha F_s^1 + (1-\alpha) F_s^0]) ds \right] \\ &= \max_{i, \tau} \alpha E \left[\int_0^\tau e^{-r(s-t)} (\hat{Y}_s^i - \hat{c} F_s^1) ds \right] + (1-\alpha) E \left[\int_0^\tau e^{-r(s-t)} (\hat{Y}_s^i - \hat{c} F_s^0) ds \right] \\ &\leq \alpha \max_{i, \tau} E \left[\int_0^\tau e^{-r(s-t)} (\hat{Y}_s^i - \hat{c} F_s^1) ds \right] + (1-\alpha) \max_{i, \tau} E \left[\int_0^\tau e^{-r(s-t)} (\hat{Y}_s^i - \hat{c} F_s^0) ds \right] \\ &= \alpha V(Y, F_1) + (1-\alpha) V(Y, F_0), \end{aligned}$$

establishing the convexity of the no trade value function with investment. ■

With an endogenous investment choice $i_t \in [\mu_0, \mu]$, the firm's profitability (EBIT) evolves as $dY_t = i_t Y_t dt + \sigma Y_t dZ_t$. The firm is generating free cash flows of $\hat{Y}_t^i dt = (1-\bar{\pi}) Y_t dt + \kappa(\mu - i_t) Y_t dt$ over the period of $(t, t + dt)$, and the normalized no trade value function $\hat{v}(\cdot)$ satisfies the HJB,

$$(r + \xi) \hat{v}(y) = \max_{i \in [\mu_0, \mu]} (1-\bar{\pi})(y-c) - \xi + \kappa(\mu - i)y + (i + \xi)y \hat{v}'(y) + \frac{1}{2} \sigma^2 y^2 \hat{v}''(y).$$

Investment is therefore optimal if and only if $\hat{v}'(y) \geq \kappa$. Convexity of the value function together with $\kappa < \phi$ therefore implies it is optimal to invest whenever y exceeds some threshold y_i^{inv} . Because at default $\hat{v}'(y_b^{inv}) = 0 < \kappa$, the option to stop investing is valuable and hence $y_b^{inv} < y_b$.

To characterize \hat{v} , it is easiest to consider separately the value functions (v^I, v^{NI}) in the investment and no investment regions, respectively. The value function v^I can be solved for using the methods of Section II; now, shareholders have the option to stop investing rather than to default.

Recall $\phi \equiv \frac{1-\bar{\pi}}{r-\mu}$ and $\gamma \equiv \frac{(\mu + \xi - 0.5\sigma^2) + \sqrt{(\mu + \xi - 0.5\sigma^2)^2 + 2\sigma^2(r + \xi)}}{\sigma^2} > 0$. Given the

value function $v^{NI}(\cdot)$ with $v^{NI}(y_b) > 0$ (because $y_b^{inv} < y_b$),

$$\begin{aligned} v^I(y) &= \max_{\hat{y}_i} \phi y - \rho + \left(\frac{y}{\hat{y}_i}\right)^{-\gamma} \left(v^{NI}(\hat{y}_i) - (\phi\hat{y}_i - \rho)\right) \\ &= \phi y - \rho + y^{-\gamma} \left[\max_{\hat{y}_i} \hat{y}_i^\gamma \left(v^{NI}(\hat{y}_i) - \phi\hat{y}_i + \rho\right) \right] \\ &> \phi y - \rho + y^{-\gamma} \left[y_b^\gamma (-\phi y_b + \rho) \right] = v(y), \end{aligned}$$

where $v(y)$ is the value function from Section II without the investment option. Therefore,

$$v^I(y) = \phi y - \rho - \Lambda_I \left(\frac{y}{y_b}\right)^{-\gamma} (\phi y_b - \rho) \text{ with } \Lambda_I = \frac{\max_{\hat{y}_i} \hat{y}_i^\gamma \left(v^{NI}(\hat{y}_i) - \phi\hat{y}_i + \rho\right)}{y_b^\gamma (\rho - \phi y_b)} > 1.$$

Note that $\Lambda_I > 1$ implies $v^I(y) > v^{I'}(y) \geq \kappa > 0$ for $y \geq y_i^{inv}$. Because $v^I(y_b) = 0$, we therefore must have $y_i^{inv} > y_b$.

We now solve for v^{NI} explicitly as follows. The HJB in the no investment region implies

$$v^{NI}(y) = \phi_d y - \rho + A_d y^{-\gamma_d} + B_d y^{\eta_d},$$

where $\phi_d \equiv \frac{1-\bar{\pi} + \kappa(\mu - \mu_0)}{r}$, and $\eta_d \equiv \gamma_d + 1 - 2\xi\sigma^{-2} > 1$ with

$$\gamma_d \equiv \frac{(\mu_0 + \xi - 0.5\sigma^2) + \sqrt{(\mu_0 + \xi - 0.5\sigma^2)^2 + 2\sigma^2(r + \xi)}}{\sigma^2} > 0.$$

To solve the model, note that smooth-pasting and the optimality condition for investment imply

$$v^I(y_i^{inv}) = v^{NI}(y_i^{inv}) \text{ and } v^{I'}(y_i^{inv}) = v^{NI'}(y_i^{inv}) = \kappa.$$

Combined with the usual default boundary conditions,

$$v^{NI}(y_b^{inv}) = v^{NI'}(y_b^{inv}) = 0,$$

we have five equations to solve for five unknowns $\{\Lambda_I, A_d, B_d, y_i^{inv}, y_b^{inv}\}$. The solution to this system can be characterized as follows. The default boundary y_b^{inv} can be solved from the following uni-dimensional nonlinear equation:

$$\left[\frac{(\rho\gamma_d - \phi_d y_b^{inv} (1 + \gamma_d))(y_b^{inv})^{-\eta_d}}{(1 + \gamma_d)(\phi - \phi_d) + (\gamma_d / \gamma - 1)(\phi - \kappa)} \right]^{\frac{1}{1 - \eta_d}} = \left[\frac{(\rho\eta_d - \phi_d y_b^{inv} (\eta_d - 1))(y_b^{inv})^{\gamma_d}}{(\eta_d - 1)(\phi - \phi_d) + (\eta_d / \gamma + 1)(\phi - \kappa)} \right]^{\frac{1}{1 + \gamma_d}}$$

Once we obtain y_b^{inv} , the remaining unknowns are

$$y_i^{inv} = \left(\frac{(\rho\eta_d - \phi_d y_b^{inv} (\eta_d - 1))(y_b^{inv})^{\gamma_d}}{(\eta_d - 1)(\phi - \phi_d) + (\eta_d / \gamma + 1)(\phi - \kappa)} \right)^{\frac{1}{1 + \gamma_d}}, \quad \Lambda_I = \left(1 - \frac{\kappa}{\phi} \right) \left(\frac{y_i^{inv}}{y_b} \right)^{1 + \gamma},$$

$$A_d = -\frac{\phi_d y_b^{inv} (\eta_d - 1) - \rho\eta_d (y_b^{inv})^{\gamma_d}}{\gamma_d + \eta_d}, \quad B_d = -\frac{\phi_d y_b^{inv} (1 + \gamma_d) - \rho\gamma_d (y_b^{inv})^{-\eta_d}}{\gamma_d + \eta_d}.$$

Given the solution for (v^I, v^{NI}) , we can then calculate the equilibrium debt price $p = yv' - v$ and

issuance rate $g^* = \frac{\bar{\pi}c}{y^2 v''}$ as in the baseline model.
