This paper considers the estimation of dynamic causal effects using a proxy structural vector-autoregressive model with possibly nonstationary regressors. We provide general conditions under which the asymptotic normal approximation remains valid. In this case, the asymptotic variance depends on the persistence property of each series. We further provide a consistent asymptotic covariance matrix estimator that requires neither knowledge of the persistence properties of the variables nor pretests for nonstationarity. The proposed consistent covariance matrix estimator is robust and is easy to implement in practice. When all regressors are indeed stationary, the method becomes the same as the standard procedure.

1. INTRODUCTION

To study the dynamic causal effects of macroeconomic shocks, it has become increasingly popular to use external instruments (proxies) for the identification and estimation of structural vector-autoregressive (SVAR) models, following Stock and Watson (2012) and Mertens and Ravn (2013). These instruments are constructed with information outside of the system, and their correlation with the structural shocks is used for identification of dynamic causal effects—impulse response functions (IRFs). Different from identification restrictions within the SVAR system, these external instruments can be viewed as external sources of variation that provide quasi experiments to identify causal effects (Stock and Watson, 2018). These analytical frameworks typically assume that the external

© The Author(s), 2020. Published by Cambridge University Press.
instruments, the structural shocks, and all the variables in the SVAR system are stationary and conduct inference with stationary time series.

This paper is concerned with possible nonstationarity and its impact on the external-instrument estimation of SVAR models (SVAR-IV), also known as proxy SVAR models. For example, Gertler and Karadi (2015) use the SVAR-IV approach to estimate the dynamic causal effects of a monetary policy, where the baseline SVAR model includes log industrial production, log consumer price index, 1-year government bond rate, and a credit spread. The first two variables are often regarded as nonstationary. Vector autoregressions (VARs) with nonstationary processes typically involve nonstandard inference (Park and Phillips, 1989a, 1989b; Sims, Stock, and Watson, 1990; Toda and Phillips, 1993). This leads us to the following questions. Is the standard inference still valid if we conduct the SVAR-IV estimation directly with these possibly nonstationary time series as in Gertler and Karadi (2015)? Do we need to first transform them to stationary time series before the analysis? What if some variables are cointegrated with an unknown rank and some variables are highly persistent but do not have exactly unit roots?

To answer the above questions, we provide several robust results for SVAR-IV estimation with possible nonstationary variables in the VAR system. The system may contain unit roots, local-to-unity processes, cointegration, or only stationary variables (Phillips, 1987, 1988; Engle and Granger, 1987). These robust results do not require knowing the persistence property of any series or knowing the cointegrating relationship. Therefore, we avoid the pretest or postmodel-selection bias (Leeb and Pötscher, 2005). Such bias could be particularly prominent in the presence of local-to-unity variables (Elliott, 1998).

First, we show that the SVAR-IV estimator of the IRFs has an asymptotic normal distribution as long as the system contains some stationary variables or cointegration, or its lag order is larger than one. The asymptotic variance, however, depends on the persistence property, including the classification of stationary variables and the cointegration relationship among nonstationary variables. Second, we provide a consistent estimator of the asymptotic covariance matrix, without using knowledge of the persistence property. Thus, the $t$ and Wald statistics based on this consistent covariance estimator have standard asymptotic distributions. Third, we show that the optimal weighting matrix under overidentification depends on the persistence property. Nevertheless, we again provide a consistent estimator of the optimal weighting matrix without using knowledge of the persistence property. We maintain the assumption that the external instruments and the structural shocks are stationary, which is well justified in relevant applications. We also assume that the instruments are strong, and we do not allow for weak instruments as in Montiel Olea, Stock, and Watson (2018).

The robust results in this paper stem from the fact that coefficient estimates of the nonstationary regressors converge at a faster rate and its influence is asymptotically negligible when compared to that from the stationary regressors. This phenomenon has been studied and utilized extensively in the nonstationary VAR literature. Sims et al. (1990) show that a normal approximation is valid in a VAR model with unit

Our work contributes to the nonstationary VAR literature by obtaining the asymptotic normality of structural IRFs estimated using external instruments. The SVAR-IV estimation has a generated-regressor issue, where the unobserved errors are replaced by the estimation residuals based on possibly nonstationary regressors. We show that the generated-regressor issue has an impact on the asymptotic distribution and leads to an optimal weighting matrix different from the standard two-stage least-squares (2SLS) weighting matrix even in the conditional homoskedastic context.

The present paper is also related to the literature about inference on structural IRFs. Confidence bands for IRFs with exact unit roots and local-to-unity processes are considered by Phillips (1998), Wright (2000), Gospodinov (2004), Pesavento and Rossi (2007), and Mikusheva (2012), among others. Unlike the nonstandard inference in these papers, inference based on the asymptotic normality is valid in the present context. Although we focus on IRFs for a single horizon, our results provide a basis for joint inference over multiple horizons considered by Inoue and Kilian (2016) and Montiel Olea and Plagborg-Møller (2019).

The rest of the paper is organized as follows. Section 2 presents the structural VAR model and the estimation procedure. Section 3 studies the asymptotic distribution of the contemporaneous and dynamic IRFs based on the SVAR-IV estimation. Section 4 provides a robust consistent covariance matrix estimator without requiring knowledge of persistence properties. Section 5 proposes an optimal weighting matrix and provides asymptotic results when the optimal weighting matrix is used. Section 6 presents Monte Carlo simulation results, and Section 7 concludes.

2. STRUCTURAL VAR AND ESTIMATION

In this section, we provide the structural VAR model and the estimation procedure. The estimation procedure is the same as the standard practice, where all variables are assumed to be stationary. Let \( \{Y_t : t = -p + 1, \ldots, T\} \) be an \( r \times 1 \) vector of observed variables that follows a structural VAR model

\[
Y_t = d + \sum_{j=1}^{p} \Phi_j Y_{t-j} + \eta_t \quad \text{and} \quad \eta_t = H \varepsilon_t, \tag{2.1}
\]

where \( \Phi_j \) is an \( r \times r \) coefficient matrix for \( j = 1, \ldots, p \), \( \eta_t \) is the reduced-form error, \( \varepsilon_t = (\varepsilon_{1t}, \ldots, \varepsilon_{rt})' \) is the vector of structural shocks, and \( H \) is an \( r \times r \) invertible
Suppose the structural shock of interest is $\varepsilon_{it}$ for some $i = 1, \ldots, r$. To study the IRFs with respect to $\varepsilon_{it}$, we study the estimation of the $i$th column of $H$, denoted by $h = (h_1, \ldots, h_r)'$, with external instruments $\{Z_t = (z_{1t}, \ldots, z_{kt})' \in R^k : t = 1, \ldots, T\}$. These external instruments are assumed to satisfy (i) $E(Z_t \varepsilon_{it}) = \alpha \neq 0_k$ and (ii) $E(Z_t \varepsilon_{jt}) = 0_k$ for $j \neq i$. Condition (i) ensures that the instruments are relevant, and condition (ii) requires that the instruments are orthogonal to other structural shocks. Under these conditions, the instruments satisfy

$$E(\eta_t Z_t') = E(H \varepsilon_t Z_t') = h \alpha' \in R^{r \times k}. \quad (2.2)$$

We need at least one instrument. The system is overidentified if $k > 1$.

We allow the series in $Y_t$ to display different degrees of persistence. From a practical perspective, one does not have to know the persistence level of any series to conduct the estimation and inference procedure proposed in this paper. For our theoretical analysis, we write $Y_t = [Y_{1t}', Y_{2t}', Y_{3t}']'$ and assume that $Y_{1t}$ and $Y_{2t}$ follow a local-to-unity vector process and may be cointegrated whereas $Y_{3t}$ follows a stationary vector process, as specified in (3.1) below. Further assumptions on the form of nonstationarity and other regularity conditions for the model are also given in Section 3. The literature typically assumes that the shock of interest is the first shock $\varepsilon_{1t}$ without loss of generality in a stationary VAR system. Here, we denote the shock of interest by $\varepsilon_{it}$ to make it clear that it could be the shock associated with either the nonstationary or the stationary series.

Given that $\alpha$ is unknown and $\alpha \neq 0$, the moment conditions in (2.2) only identify $h$ up to a scale constant. We normalize the $i$th element of $h$ to be 1, i.e., $h_i = 1$. This normalization pins down the scale of the IRFs by standardizing the contemporaneous effect of the target shock (e.g., an oil price shock) on the corresponding variable (e.g., the oil price). In the existing literature, $\varepsilon_{1t}$ is often assumed to be the structural shock of interest, and the first element of $h$ is normalized to be 1.

Removing the constant 1 from $h$, we define the parameter

$$\theta = [h_1, \ldots, h_{i-1}, h_{i+1}, \ldots, h_r]' \in R^{r-1}. \quad (2.3)$$

Using $h_i = 1$, (2.2) is equivalent to the moment conditions

$$E[(\eta_{i-1,t} - \theta \eta_{i,t}) \otimes Z_t] = 0 \in R^{(r-1)k}, \quad (2.4)$$

where $\eta_{i,t}$ is the $i$th element of $\eta_t$ and $\eta_{i-1,t} = [\eta_{1,t}, \ldots, \eta_{i-1,t}, \eta_{i+1,t}, \ldots, \eta_{r,t}]'$ is the rest of $\eta_t$ with $\eta_{i,t}$ removed. Below we study the estimation of $\theta$ based on the moments in (2.4).

Because $\eta_t$ is unobserved, we estimate the VAR model in (2.1) by OLS and use the residual $\tilde{\eta}_t = (\tilde{\eta}_{1t}, \ldots, \tilde{\eta}_{rt})'$ to construct the sample moment conditions. Let $\tilde{\eta}_{i-1,t}$ and $\tilde{\eta}_{i,t}$ denote the counterparts of $\eta_{i-1,t}$ and $\eta_{i,t}$, respectively. We estimate $\theta$ by

---

1We focus on the model without a linear time trend. The presence of a linear time trend does not change our results qualitatively, however.
minimizing the generalized method of moments (GMM) criterion
\[ Q_T(\theta) = \bar{g}_T(\theta)' W_T \bar{g}_T(\theta), \]
where
\[ \bar{g}_T(\theta) = \frac{1}{T} \sum_{t=1}^{T} [ (\eta_{-i,t} - \theta \eta_{i,t}) \otimes Z_t ] \]
and \( W_T \) is the weighting matrix. The first order condition gives the GMM estimator
\[ \hat{\theta} = (A_T W_T A_T')^{-1} A_T W_T G_T, \]
where
\[ A_T = I_{r-1} \otimes \left( T^{-1} \sum_{t=1}^{T} \eta_{i,t} Z_t' \right) \quad \text{and} \quad G_T = T^{-1} \sum_{t=1}^{T} (\eta_{-i,t} \otimes Z_t). \]
If \( W_T = I_{r-1} \otimes (T^{-1} \sum_{t=1}^{T} Z_t Z_t')^{-1} \), \( \hat{\theta} \) is the equation-by-equation 2SLS estimator.
We provide the optimal weighting matrix in Section 5 below.

3. ASYMPTOTIC RESULTS

We assume that \( Y_t \) in the structural VAR model (2.1) is generated by the following reduced-form representation. The structural model defines the IRFs, whereas the reduced-form representation makes it clear that the system can allow for both (near) unit roots and cointegration. We also impose further assumptions on the reduced-form model. The reduced-form representation is

\[
\begin{align*}
Y_t &= c + Y_t^*, \\
Y_{1t}^* &= \left( I_{r_1} + \frac{1}{T} C \right) Y_{1,t-1}^* + u_{1t} \in R^{r_1}, \\
Y_{2t}^* &= Q Y_{1t}^* + u_{2t} \in R^{r_2}, \\
Y_{3t}^* &= u_{3t} \in R^{r_3}, \\
\Psi(L) u_t &= e_t, 
\end{align*}
\]

where \( c = [c_1', c_2', c_3']', Y_t = [Y_{1t}', Y_{1t}', Y_{3t}']', Y_t^* = [Y_{1t}^*, Y_{2t}^*, Y_{3t}^*]' \), \( C \) is an \( r_1 \times r_1 \) diagonal matrix with nonpositive diagonal elements, \( Q \) is an \( r_2 \times r_1 \) matrix, \( \Psi(L) = I_r - \Psi_1 L - \cdots - \Psi_{p-1} L^{p-1} \) is a \( (p-1) \)th-order lag polynomial, \( u_t = [u_{1t}', u_{2t}', u_{3t}']' \), and \( e_t = [e_{1t}', e_{2t}', e_{3t}']' \).

---

2In practice, variables in the structural model could be a rotation of those in the reduced-form model (3.1), because (3.1) is just one way to specify a cointegrating relationship. In addition, we could include additional stationary variables \( Y_{1,t-1}^* \) and \( Y_{2,t-1}^* = Q Y_{1,t-1}^* \) in (3.1). A rotation of the cointegrating system and adding stationary variables in (3.1) do not change results in the paper. The reduced-form model (3.1) is sufficient to show that the effects of unit roots and cointegration are both negligible in the presence of any stationary components.

3We assume that \( r_2 = 0 \) if \( r_1 = 0 \) and that \( Q \) does not have a row of zeros. If \( r_1 = 0 \) and \( r_2 = 0 \), we specify \( \Psi(L) \) as a \( p \)th-order polynomial.
We also assume that \( Z_t \) follows a linear process
\[
Z_t = \mu_Z + \Xi(L)v_t, \quad \text{where} \quad \Xi(L) = \sum_{j=0}^{\infty} \Xi_j L^j. \tag{3.2}
\]

**Assumption LP.**

(i) The roots of \( \Psi(L) \) are all outside the unit circle.

(ii) \( \Xi_0 = I_k, \, \Xi(1) \) has full rank, \( \sum_{j=0}^{\infty} j^2 \| \Xi_j \|^2 < \infty \).

(iii) \( \bar{\epsilon}_t = [\epsilon'_t, v'_t]' \) is an i.i.d. \((r+k) \times 1\) vector with mean zero, \( E(\bar{\epsilon}_t \bar{\epsilon}'_t) = \Sigma \) is positive definite, fourth moments of \( \bar{\epsilon}_t \) are finite, and \( \epsilon_t \) is homoskedastic conditional on \( v_t \).

We show in the Appendix that the model in (3.1) can be rearranged and written in an error correction form:
\[
\Delta Y_t = A_1(Y_{1,t-1} - c_1) + A_2 + A_3 D_t + \eta_t, \tag{3.3}
\]
where \( Y_{1,t-1} \) is the nonstationary lag,
\[
D_t = [(Y_{2,t-1} - c_2 - Q(Y_{1,t-1} - c_1))', (Y_{3,t-1} - c_3)', \Delta Y'_{t-1}, \ldots, \Delta Y'_{t-p+1}]' \in \mathbb{R}^{r_p - r_1} \tag{3.4}
\]
is a collection of all zero-mean stationary lags, \( A_1, A_2, \) and \( A_3 \) are coefficient matrices, and
\[
\eta_t = P \epsilon_t, \quad \text{for} \quad P = \begin{bmatrix}
I_{r_1} & 0 & 0 \\
Q & I_{r_2} & 0 \\
0 & 0 & I_{r_3}
\end{bmatrix}. \tag{3.5}
\]

Let
\[
x_t = [(Y_{1,t-1} - c_1)', 1, D_t]'
\]
denote the regressors in (3.3). An intercept is included in (3.3) so that the regressors in (3.3) and the regressors in (2.1) have a one-to-one transformation, given in (3.15) below. This equivalent representation implies that the least-squares residual \( \tilde{\eta}_t \) obtained from the VAR model in (2.1) is numerically equivalent to that obtained from regressing \( \Delta Y_t \) on \( x_t \). The model in (2.1) is used for practical estimation to obtain the residual, whereas the model in (3.3) is used for theoretical analysis of the estimator.

Note that (3.5) shows the link between the reduced-form error \( \eta_t \) in (2.1) and the innovation \( e_t \) in (3.1). The following assumption formulates the link between the structural shock \( \epsilon_t \) and reduced-form error \( \eta_t \) and provides the condition to ensure the instrument validity and instrument relevance. These conditions are also discussed in Section 2 when the instruments are introduced for the estimation method.

**Assumption IV.** The structural shock \( \epsilon_t \) is linked to the reduced-form error \( \eta_t = P \epsilon_t \) by the linear transformation
\[
\eta_t = H \epsilon_t
\]
for some nonsingular matrix $H$ and
\[ E(Z_t\varepsilon'_t) = [0_{k \times (i-1)}, \alpha, 0_{k \times (r-i)}], \]
where $\alpha \neq 0$.

Assumption LP and $\varepsilon_t = H^{-1}P\epsilon_t$ imply that $E(\varepsilon_t|Z_{t-1}, Z_{t-2}, \ldots) = 0$, i.e., the structural shock is uncorrelated with the lags of instruments. This implication is consistent with the structural VAR literature, where the structural shocks are unpredictable conditional on the historical information. In addition, we allow $Z_t$ to be correlated with lags of $\varepsilon_t$. By the linear process for $Z_t$ and Assumption LP, we can obtain
\[ E[Z_t\varepsilon'_{t-s}] = E[(\mu_Z + \Xi(L)v_t)e'_{t-s}] = \Xi_s E[v_{t-s}\varepsilon'_{t-s}], \]
which can take nonzero value if $\Xi_s \neq 0$ for $s > 0$.

We have the following weak convergence results following Phillips and Solo (1992).

**LEMMA 1.** Suppose Assumption LP holds. Then,
\begin{enumerate}
  \item \[ T^{-\frac{1}{2}} \sum_{t=1}^{[sT]} e_t \Rightarrow \begin{bmatrix} B_e(s) \\ B_v(s) \end{bmatrix} = \Sigma^{1/2} \begin{bmatrix} W_e(s) \\ W_v(s) \end{bmatrix}, \]
where $W_e(s)$ and $W_v(s)$ are $r \times 1$ and $k \times 1$ standard Brownian motions, respectively, and they are independent of each other.
  \item \[ T^{-\frac{1}{2}} \sum_{t=1}^{[sT]} u_t \Rightarrow B_u(s) = [\Psi(1)]^{-1} B_e(s). \]
  \item \[ T^{-\frac{1}{2}} \sum_{t=1}^{[sT]} \eta_t \Rightarrow B_\eta(s) = PB_e(s). \]
  \item \[ T^{-\frac{1}{2}} \sum_{t=1}^{[sT]} (Z_t - \mu_Z) \Rightarrow B_z(s) = \Xi(1) B_v(s). \]
\end{enumerate}

Define
\[ \Gamma_{DD} = \lim_{T \to \infty} E(D_tD'_t), \]
\[ \Gamma_{DZ} = \lim_{T \to \infty} E[D_t(Z_t - \mu_Z)'], \]
\[ \Gamma_{ZZ} = E[(Z_t - \mu_Z) (Z_t - \mu_Z)'], \Gamma = [\Gamma_{DZ} : \Gamma_{DD}], \]
\[ \Gamma_{\eta Z} = E(\eta_t Z_t'), \Lambda = \sum_{h=1}^\infty E(u_{1,t}Z'_{t+h}), \]
\[ \gamma = E(\eta_t \otimes Z_t), \]
\[ \Sigma_\eta = E[\eta_t \otimes \eta_t'], \]
\[ \Omega = \begin{bmatrix} \Sigma_\eta \otimes \Gamma_{DD} & \Sigma_\eta \otimes \Gamma_{DZ} \\ \Sigma_\eta \otimes \Gamma'_{DZ} & \Sigma_\eta \otimes \Gamma_{ZZ} - \gamma \gamma' \end{bmatrix}. \tag{3.7} \]
In some of these definitions, we have $T \to \infty$ built-in, because $D_t$ is a triangular array due to the local-to-unity process.

**Assumption R1.**

(i) $D_t$ in (3.4) is nonempty, i.e., $r_2 > 0$, or $r_3 > 0$, or $p > 1$.

(ii) The matrices $\Gamma, \Gamma_{nZ}, \Omega$ all have full rank.

Assumption R1(i) is a key condition for the results in the paper. It ensures that the IRFs depend on some stationary regressors $D_t$ that can only be estimated at the $n^{1/2}$ rate. For this condition to hold, we provide three sufficient conditions: (i) there is a cointegrating relationship, i.e., $r_2 > 0$; (ii) a subvector of $y_t$ is stationary, i.e., $r_3 > 0$; and (iii) the lag order of the VAR model is greater than 1, i.e., $p > 1$.

Assumption R1(ii) provides regularity conditions that some covariance matrices are full rank. The matrix $\hat{W}, \hat{W}_\eta Z, \Omega_1$ all have full rank means that $Z_t$ and $\eta_t$ are correlated, which holds if the $(i, i)$th element of $H$ is nonzero and Assumption IV holds with $\alpha \neq 0_k$.

Let $J_c(s)$ denote an $r_1 \times 1$ vector Ornstein–Uhlenbeck process such that

$$dJ_c(s) = CJ_c(s)ds + dB_u(s),$$

where $B_u(s)$ is the first $r_1 \times 1$ subvector of $B_u(s)$. Let

$$\Upsilon_T = \begin{bmatrix} T^{1/2} J_1 & 0 \\ 0 & I_{p-r_1+1} \end{bmatrix}. \tag{3.9}$$

**Lemma 2.** Suppose Assumptions LP and R1 hold. Then,

(a) $$T^{-1} \sum_{t=1}^T \Upsilon_T^{-1} x_t x_t' \Upsilon_T^{-1} \to_d \begin{bmatrix} \int_0^1 J_c(s)J_c(s)' ds & \int_0^1 J_c(s)ds & 0 \\ \int_0^1 J_c(s)' ds & 1 & 0 \\ 0 & 0 & \Gamma_{DD} \end{bmatrix}. \tag{3.8}$$

(b) $$\begin{bmatrix} T^{-1} \sum_{t=1}^T Y_{1,t-1}' (Z_t - \mu Z)' \\ T^{-1} \sum_{t=1}^T (Z_t - \mu Z)' \\ T^{-1} \sum_{t=1}^T D_t (Z_t - \mu Z)' \\ T^{-1} \sum_{t=1}^T (Z_t - \mu Z)(Z_t - \mu Z)' \end{bmatrix} \to_d \begin{bmatrix} \int_0^1 J_c(s)B_z(s)' + \Lambda_{1Z} \\ 0_{1 \times k} \\ \Gamma_{DZ} \\ \Gamma_{ZZ} \end{bmatrix}. \tag{3.9}$$

(c) $$\begin{bmatrix} T^{-1/2} \sum_{t=1}^T Y_{1,t-1}' \\ T^{-1} \sum_{t=1}^T Y_{1,t-1}' \eta_t' \end{bmatrix} \to_d \begin{bmatrix} \int_0^1 J_c(s)ds \\ \int_0^1 J_c(s)dB_\eta(s)' \end{bmatrix}. \tag{3.10}$$
(d) \[
T^{-\frac{1}{2}} \sum_{t=1}^{T} \left( \eta_t \otimes D_t \right) \rightarrow_d \left( \xi_D \right) \sim N(0, \Omega).
\]

Let \( S_\theta \) be an \((r - 1) \times r\) matrix such that
\[
S_\theta \eta_t = \eta_{t-1} - \theta \eta_{t-1}.
\]

By definition, it takes the form
\[
S_\theta = \left[ I_{r-1}(1 : t-1) : -\theta : I_{r-1}(t : r-1) \right],
\]

where \( I_{r-1}(1 : t-1) \) collects the first \((t - 1)\) columns of \( I_{r-1} \) and \( I_{r-1}(t : r-1) \) collects the last \((r - t)\) matrix of \( I_{r-1} \).

**Theorem 1.** Suppose Assumptions LP, IV, and R1 hold and \( W_T \rightarrow_p W \). Then,

(a) \[
T^{\frac{1}{2}} (\hat{\theta} - \theta) \rightarrow_d (AWA')^{-1} AW \cdot \left[ -\left( S_\theta \otimes K \right) \xi_D + \left( S_\theta \otimes I_k \right) \xi_Z \right],
\]

where \( A = I_{r-1} \otimes \Gamma_{\eta Z} \) and \( K = \Gamma_{DZ} \Gamma_{DD}^{-1} \).

(b) The optimal choice of the weighting matrix is \( V^{-1} \), where
\[
V = B \Omega B' \quad \text{and} \quad B = [-S_\theta \otimes K : S_\theta \otimes I_k].
\]

Because \( \Gamma_{DZ} \) is nonzero in general, replacing \( \eta \) with \( \tilde{\eta} \) affects the asymptotic distribution of \( \hat{\theta} \).

Next, we study the asymptotic distribution of the IRFs. We start with the moving average (MA) coefficients \( \Theta_s \) in the vector moving average (VMA) representation of (2.1), i.e.,
\[
Y_t = d + \eta_t + \sum_{s=1}^{\infty} \Theta_s \eta_{t-s}.
\]

By definition, \( \Theta_s = I_r \) for \( s = 0 \). Define the companion matrix for the VAR presentation in (2.1) as
\[
F = \begin{bmatrix}
\Phi_1 & \cdots & \Phi_{p-1} & \Phi_p \\
I_r & \cdots & 0 & 0 \\
\vdots & \cdots & \vdots & \vdots \\
0 & \cdots & I_r & 0
\end{bmatrix}.
\]

Then, \( \Theta_s = M' F' M \) for \( M' = [I_r, 0, \ldots, 0] \). We estimate \( \Theta_s \) by \( \tilde{\Theta}_s = M' \tilde{F}' M \), where \( \tilde{F} \) is defined analogously to \( F \) but with \( \Phi_j \) for \( j = 1, \ldots, p \) replaced by their ordinary least-squares (OLS) estimator \( \tilde{\Phi}_j \) based on (2.1).
To derive the distribution of $\Theta_\delta$, we first define a matrix $L$ that transforms the regressors in (2.1), denoted by $X_t$, to those in (3.3), denoted by $x_t$, i.e.,

$$
x_t \equiv \begin{bmatrix} Y_{1,t-1} - c_1 \\ 1 \\ D_t \\ Y_{t-p} \end{bmatrix} = L \begin{bmatrix} 1 \\ Y_{t-1} \\ \vdots \\ Y_{t-p} \end{bmatrix} \equiv LX_t.
$$

(3.14)

By the definition of $D_t$ in (3.4), we have

$$\begin{align*}
L &= \begin{bmatrix}
-c_1 & I_{r_1} & 0 & 0 & 0 & \cdots & 0 \\
1 & 0 & 0 & 0 & 0 & \cdots & 0 \\
Qc_1 - c_2 & -Q & I_{r_2} & 0 & 0 & \cdots & 0 \\
-c_3 & 0 & 0 & I_{r_3} & 0 & \cdots & 0 \\
I_{r_1} & 0 & 0 \\
0 & 0 & I_{r_2} & 0 & -I_r & \cdots & 0 \\
0 & 0 & I_{r_3} \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
0 & 0 & 0 & 0 & 0 & I_r & -I_r
\end{bmatrix}.
\end{align*}
$$

(3.15)

Note that $L$ is an invertible square matrix that provides a one-to-one transformation between $x_t$ and $X_t$. Because the VAR model in (2.1) can be equivalently written as in (3.3), the OLS estimators of the coefficients in (2.1) and those in (3.3) satisfy

$$
[d : \Phi_1 - I_r : \Phi_2 : \cdots : \Phi_p] = [\tilde{A}_1 : \tilde{A}_2 : \tilde{A}_3]L.
$$

(3.16)

Thus, we can study the distribution of $\Theta_\delta$ using the equivalent representation in (3.3) and the asymptotic results in Lemma 2.

Define

$$\begin{align*}
\bar{L} &= \begin{bmatrix}
-Q & 0 & I_{r_1} & 0 & 0 & \cdots & 0 \\
I_{r_2} & 0 & 0 & I_{r_2} & 0 & \cdots & 0 \\
0 & I_{r_3} & 0 & 0 & I_{r_3} & \cdots & 0 \\
\vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\
0 & 0 & 0 & 0 & 0 & 0 & -I_r
\end{bmatrix}.
\end{align*}
$$

(3.17)
which is an \(rp \times (rp - r_1)\) lower-right submatrix of \(L'\) used in the transformation above. Define

\[
\mathcal{R} = \sum_{i=0}^{s-1} \Theta_{s-i} \otimes (M_i'F_i) \quad \text{and} \quad \mathcal{J} = \mathbb{L}\Gamma^{-1}_{DD}.
\]

**Assumption R2.** The matrix \(\mathcal{R}\) has full rank.

Assumption R2 is the typical rank condition necessary for frequentist inference on IRFs obtained from the VAR slope parameters. It rules out the problem pointed out by Benkwitz et al. (2000), for example.

**THEOREM 2.** Suppose Assumptions LP, IV, and R1–R2 hold. Then, for \(s \geq 1\),

\[
T^{\frac{1}{2}} \text{vec}(\widetilde{\Theta}'_s - \Theta'_s) \rightarrow_d \mathcal{R}(I_r \otimes \mathcal{J})\xi_D.
\]

Next, we consider the asymptotic distribution of the IRFs. For a fixed horizon \(s \geq 1\), the IRF is defined as

\[
\beta_s = \frac{\partial Y_{t+s}}{\partial \varepsilon_{i,t}} = \Theta_s h = \Theta_s \mathbb{S}_i \begin{bmatrix} 1 \\ \theta \end{bmatrix},
\]

where

\[
\mathbb{S}_i \equiv \begin{bmatrix} 0 & I_{r-1} & 0 \\ 1 & 0 & 0 \\ 0 & 0 & I_{r-1} \end{bmatrix} \in \mathbb{R}^{r \times r}
\]

rearranges the elements of \((1, \theta')'\) such that it becomes \(h\). Let \(\overline{\mathbb{S}}_i\) denote the last \(r - 1\) columns of \(\mathbb{S}_i\). The estimator of \(\beta_s\) is

\[
\hat{\beta}_s = \Theta_s \hat{h} = \overline{\Theta}_s \overline{\mathbb{S}}_i \begin{bmatrix} 1 \\ \hat{\theta} \end{bmatrix}.
\]

Define

\[
G_{1s} = \Theta_s \overline{\mathbb{S}}_i [AWA']^{-1} AW[-\mathbb{S}_0 \otimes \mathcal{K} : \mathbb{S}_0 \otimes I_k],
\]

\[
G_{2s} = [(I_r \otimes h' ) \mathcal{R}(I_r \otimes \mathcal{J}) : 0_{r \times rk}].
\]

**Assumption R3.** \(G_{1s} + G_{2s}\) has rank \(r\).

Assumption R3 is the rank condition for the delta method. It is similar to Assumption R2 and rules out the Benkwitz et al. (2000) problem.

**THEOREM 3.** Suppose that Assumptions LP, IV, and R1–R3 hold and \(W_T \rightarrow_p W\), then

\[
T^{\frac{1}{2}} (\hat{\beta}_s - \beta_s) \rightarrow_d \mathcal{N}(0, (G_{1s} + G_{2s}) \Omega (G_{1s} + G_{2s})').
\]
In the asymptotic distribution in Theorem 3, the first part associated with $G_1s$ comes from the estimation of the contemporaneous IRF $\hat{h}$, whose random elements are $\hat{\theta}$, and the second part associated with $G_2s$ comes from the estimation of the MA parameter $\hat{\Theta}_s$ for the dynamic response.

Constructing the asymptotic variance of $\hat{\beta}_s$ using sample analogs of $G_1s$, $G_2s$, and $\Omega_1$ requires one to distinguish stationary and nonstationary series in $Y_t$ and specify the cointegrating relationship among the nonstationary series. To see this, note that $K$, $J$, and $\Omega_1$ by definition are all constructed with $D_t$ defined in (3.4).

Using model selection procedures or pretests to specify $D_t$ may result in model selection errors and undesirable consequences for subsequent inference. Below we provide a consistent covariance matrix estimator that avoids this specification problem.

4. CONSISTENT COVARIANCE MATRIX ESTIMATOR

In this section, we propose a robust consistent estimator of the asymptotic variance of $\hat{\beta}_s$. The key feature is that it does not require knowing the persistence property of any series or any cointegrating relationship. It is constructed with the whole vector $Y_t$ in the VAR system, instead of the stationary regressors only. We show that it is consistent under all different forms of nonstationarity allowed in this paper.

In the estimation of the covariance matrix, the main challenge comes from the estimation of $K$, $J$, and $\Omega_1$, all of which are defined with the stationary regressors only. Without distinguishing the stationary regressors from the nonstationary ones, we use $X_t = [1, Y_{t-1}, \ldots, Y_{t-p}]'$ and propose to estimate $K$ and $J$, respectively, by

$$
\hat{K} = \hat{\Gamma}_{XX} \hat{\Gamma}_{XX}^{-1} \text{ and } \hat{J} = S_2 \hat{\Gamma}_{XX}^{-1},
$$

where

$$
\hat{\Gamma}_{XX} = \frac{1}{T} \sum_{t=1}^{T} X_t X_t',
$$

$$
\hat{\Gamma}_{ZX} = \frac{1}{T} \sum_{t=1}^{T} (Z_t - \bar{Z}_T) X_t', \quad \bar{Z}_T = \frac{1}{T} \sum_{t=1}^{T} Z_t,
$$

(4.1)

and $S_2 = [0_{r \times 1} : I_{rp}]$ is a selector matrix. Lemma 3 below shows that some proper rotation with the matrix $\Lambda$ and rescaling using the matrix $\Upsilon_T$ lead to the limits of $\hat{K}$ and $\hat{J}$ that contain $K$ and $J$ as subvectors, respectively.

Using $\hat{K}$ and $\hat{J}$, we construct

$$
\hat{G}_{1s} = \hat{\Theta}_s \hat{F}_s (A_T W_T A_T')^{-1} A_T W_T [ -S_{\hat{\theta}} \otimes \hat{K} : S_{\hat{\theta}} \otimes I_k ],
$$

$$
\hat{G}_{2s} = [(I_r \otimes \hat{h}) \hat{\Lambda} (I_r \otimes \hat{J}) : 0_{r \times rk}],
$$

(4.2)

where $S_{\hat{\theta}}$ and $\hat{h}$ are defined as $S_{\hat{\theta}}$ and $h$ with $\theta$ replaced by $\hat{\theta}$, respectively, $\hat{\Lambda} = \sum_{i=0}^{s-1} \hat{\Theta}_{s-1-i} \otimes (M' P' M')$, and $P$ is defined as $P$ with $\Phi_1, \ldots, \Phi_p$ replaced by $\Phi_1, \ldots, \Phi_p$. 

Let
\[ P = \begin{bmatrix} I_r \otimes L^{-1} \gamma_T & 0 \\ 0 & I_{rk} \end{bmatrix}. \] (4.3)

**Lemma 3.** Suppose Assumptions LP, IV, and R1 hold. Then,
\[ \hat{\gamma} L^{-1} \gamma_T \rightarrow P [0_{k \times (r_1 + 1)} : \mathcal{K}], \]
\[ \hat{\gamma} L^{-1} \gamma_T \rightarrow P [0_{p \times (r_1 + 1)} : \mathcal{J}], \]
and
\[ \hat{G}_{1s} P \rightarrow P \Pi_S (A W A')^{-1} A W [-S_\theta \otimes [0_{k \times (r_1 + 1)} : \mathcal{K}] : S_\theta \otimes I_k], \]
\[ \hat{G}_{2s} P \rightarrow P [(I_r \otimes h') R (I_r \otimes [0_{p \times (r_1 + 1)} : \mathcal{J}]) : 0_{r \times rk}]. \]

The limits of \( \hat{G}_{1s} P \) and \( \hat{G}_{2s} P \) are analogous to \( G_{1s} \) and \( G_{2s} \) but with \( \mathcal{K} \) and \( \mathcal{J} \) augmented with \( r_1 + 1 \) columns of zeros in the front. This shows that even if we do not know which series are nonstationary, their effects are asymptotically negligible after the rotation and rescaling by the matrix \( P \).

Next, we consider estimation of the covariance \( \Omega \). Using \( X_t, Z_t, \) and \( \tilde{\eta}_t \), we propose to estimate \( \Omega \) by
\[ \hat{\Omega} = \begin{bmatrix} \hat{\Sigma}_\eta \otimes \hat{\gamma}_X & \hat{\Sigma}_\eta \otimes \hat{\gamma}_X' \\ \hat{\Sigma}_\eta \otimes \hat{\gamma}_Z & \hat{\Sigma}_\eta \otimes \hat{\gamma}_Z - \hat{\gamma} \hat{\gamma}' \end{bmatrix}, \] (4.4)

where
\[ \hat{\Sigma}_\eta = T^{-1} \sum_{t=1}^{T} \tilde{\eta}_t \tilde{\eta}_t', \]
\[ \hat{\gamma} = T^{-1} \sum_{t=1}^{T} \tilde{\eta}_t \otimes Z_t. \] (4.5)

Define
\[ \gamma_{XZ} = \begin{bmatrix} 0_{(r_1 + 1) \times k} \\ \Gamma_{DZ} \end{bmatrix}. \] (4.6)

**Lemma 4.** Suppose Assumptions LP, IV, and R1 hold. Then,
\[ P^{-1} \hat{\Omega} P^{-1} \rightarrow_d \begin{bmatrix} \Sigma_\eta \otimes \mathcal{V} & \Sigma_\eta \otimes \gamma_{XZ} \\ \Sigma_\eta \otimes \gamma_{XZ}' & \Sigma_\eta \otimes \Gamma_{Z \gamma} - \gamma \gamma' \end{bmatrix}. \]
Comparing the limit of $P^{-1}\hat{\Omega}P^{-1'}$ and $\Omega$, we see that $V$ and $\gamma_{iZ}$ contain $\Gamma_{DD}$ and $\Gamma_{DZ}$ as submatrices. Theorem 4 below shows that the covariance matrix estimator is consistent, because the extra $r_1 + 1$ columns of zeros in Lemma 3 reduce $V$ and $\gamma_{iZ}$ to $\hat{\Gamma}_{DD}$ and $\hat{\Gamma}_{DZ}$, respectively.

**THEOREM 4.** Suppose Assumptions LP, IV, and R1 hold and $W_T \rightarrow_p W$. Then, 
$$(\hat{G}_{1s} + \hat{G}_{2s})\hat{\Omega}(\hat{G}_{1s} + \hat{G}_{2s})' \rightarrow_p (G_{1s} + G_{2s})\Omega(G_{1s} + G_{2s})'$$.

5. OPTIMAL GMM ESTIMATION

Following Theorem 1(b), the optimal GMM estimation uses the weighting matrix $W_T = \hat{V}^{-1}$, where $\hat{V}$ is a consistent estimator of $V = \hat{B}\Omega\hat{B}'$. Note that because of the generated regressor, the optimal weighting matrix is different from the weighting matrix implicit for the 2SLS estimator even in the absence of conditional heteroskedasticity.

We estimate $V$ by
$$\hat{V} = \hat{B}\hat{\Omega}\hat{B}'$$, where $\hat{B} = [-\hat{S}_{\theta} \otimes \hat{K} : \hat{S}_{\theta} \otimes I_k]$, \hspace{1cm} (5.1)

where $\hat{\theta}$ is a preliminary consistent estimator of $\theta$. The consistency of $\hat{V}$ follows from the same arguments used to show Theorem 4.

Let $\hat{\theta}^o$ denote the two-step GMM estimator. In the first step, we use either $I_{(r-1)k}$ or $I_{r-1} \otimes (T^{-1} \sum_{t=1}^T Z_tZ_t')^{-1}$ as the weighting matrix and compute the GMM estimator $\hat{\theta}$ following (2.6). In the second step, we compute $\hat{V}$ with $\hat{\theta}$ and obtain the GMM estimator $\hat{\theta}_o$ with weighting matrix $\hat{V}^{-1}$. Let $\hat{\beta}_s^o$ denote the IRF calculated with $\hat{\theta}_o$.

The following theorem summarizes the properties of the optimal GMM estimator.

**THEOREM 5.** Suppose Assumptions LP, IV, R1–R3 hold. Then,

(a) $\hat{V} \rightarrow_p V$.
(b) $T^{1/2}(\hat{\theta}^o - \theta) \rightarrow_d N(0, [AV^{-1}A']^{-1})$.
(c) $T^{1/2}(\hat{\beta}_s^o - \beta_s) \rightarrow_d N(0, (G_{1s}^o + G_{2s})\Omega(G_{1s}^o + G_{2s})')$, where $G_{1s}^o$ is defined as $G_{1s}$ but with $W$ replaced with $V^{-1}$.

The asymptotic covariance of $\hat{\theta}^o$ can be consistently estimated with $A$ and $V$ replaced by $A_T$ and $\hat{V}$, respectively. The asymptotic covariance of $\hat{\beta}_s^o$ can be consistently estimated following Theorem 4 with $W_T$ replaced by $\hat{V}^{-1}$.

The $t$ statistic and the Wald statistic based on the consistent covariance estimator have asymptotic normal and chi-square distribution, respectively.

Finally, it is worth mentioning that although all the results are robust to the presence of nonstationary time series, neither the estimators nor their consistent covariance estimators require practitioners to specify which series are stationary.
The robustness condition holds as long as $Y_t$ contains stationary or cointegrated regressors or the VAR order is larger than one.

6. SIMULATIONS

To study the finite-sample performance of inference based on the asymptotic distributions derived above, we consider the following data-generating processes (DGPs):

$$u_t = \Psi_1 u_{t-1} + \Psi_2 u_{t-2} + e_t,$$

where $u_t = [u_{1t}, u_{2t}, u_{3t}]' \in R^3$, $\Psi_1 = 0.5I_3$,

$$\Psi_2 = \begin{bmatrix} 0 & 0 & 0.2 \\ 0 & 0.2 & 0 \\ 0.2 & 0 & 0 \end{bmatrix} ,$$

and $e_t \sim N(0, I_3)$ is i.i.d. over $t$. The matrix $\Psi_2$ allows for spillover effects between $u_{1t}$ and $u_{3t}$. We generate $y_{1t}^*$, $y_{2t}^*$, and $y_{3t}^*$ using two DGPs below.

DGP1: $y_{2t}^*$ is cointegrated with $y_{1t}^*$.

$$y_{1t}^* = \left(1 - \frac{C_1}{T}\right)y_{1t-1}^* + u_{1t},$$

$$y_{2t}^* = 2y_{1t}^* + u_{2t},$$

$$y_{3t}^* = u_{3t},$$

so $y_{1t}^*$, $y_{2t}^*$, and $y_{3t}^*$ correspond to $Y_{1t}^*$, $Y_{2t}^*$, and $Y_{3t}^*$ in (3.1), respectively. The model under DGP1 contains only one root equal or close to unity. We set the drift parameter $C_1 \in [0, -2, -5, -10]$ following Stock (1991).

DGP2: $y_{2t}^*$ is not cointegrated with $y_{1t}^*$.

$$y_{1t}^* = y_{1t-1}^* + u_{1t},$$

$$y_{2t}^* = \left(1 - \frac{C_2}{T}\right)y_{2t-1}^* + u_{2t},$$

$$y_{3t}^* = u_{3t},$$

We set $C_2 \in [-2, -5, -10, -0.5T]$. For $C_2 = -2$, $-5$, or $-10$, the model under DGP2 has one unit root and a local-to-unity root. For $C_2 = -0.5T$, $y_{2t}^*$ is stationary, and the model has only one unit root.

Given $y_t^*$, we generate the observed data $Y_t = c + y_t^*$, where $y_t^* = [y_{1t}^*, y_{2t}^*, y_{3t}^*]'$ and $c = [1, 0.5, -1]'$. The reduced-form errors are given by

$$\eta_t = Pe_t,$$

where $P = \begin{bmatrix} 1 & 0 & 0 \\ 2 & 1 & 0 \\ 0 & 0 & 1 \end{bmatrix}$.
for DGP1 and \( P = I_3 \) for DGP2 following the derivation of \( P \) in (A.2). Next, we specify the matrix \( H \). Since \( \eta_t = H\varepsilon_t, \varepsilon_t \sim N(0, I_3) \), and they are i.i.d. over \( t \), the normalization \( E(\varepsilon_t, \varepsilon'_t) = I_3 \) implies \( E(\eta_t, \eta'_t) = PP' = HH' \). We set \( H \) equal to the positive definite square root of \( PP' \). Given \( H \) and \( \eta_t \), we can obtain the true values of the structural shocks by computing \( \varepsilon_t = H^{-1}\eta_t \). Finally, we generate the instrument \( Z_{jt} \) that is correlated with the \( j \)th structural shock at time \( t \) by

\[
Z_{jt} = \sqrt{1-a^2}w_{jt} + a\varepsilon_{it} + \varepsilon_{3t-1} \quad \text{for} \quad j = 1, \ldots, k,
\]

where \( w_{jt} \)'s are i.i.d. standard normal random variables, and \( a \) is set equal to \( \sqrt{2}/2 \) so that the correlation between \( Z_{jt} \) and \( \varepsilon_{jt} \) is equal to 0.5. The instruments are correlated with the lags of the structural shock, so \( \Gamma_{zd} \) is not zero and the estimation uncertainty in \( \hat{\eta} \) affects the asymptotic distribution of \( \hat{\theta} \). We set \( k = 2 \) in the simulation.

With the observed data \( Y_t \), we run an OLS estimation to fit a VAR(3) model with an intercept. The MA coefficients \( \tilde{\Theta}_T \) are computed using these OLS estimates. The residuals \( \tilde{\eta}_t \) and the instruments are used for the estimation of \( \theta \). We implement a two-step GMM estimation. In the first step, we obtain a consistent estimator of \( \theta \) using the weighting matrix \( \hat{I}_s \otimes (T^{-1}\sum_{t=1}^T Z_tZ_t')^{-1} \). Then, we reestimate \( \theta \) using the optimal weighting matrix \( \hat{V}^{-1} \), with \( V \) given by (5.1). The confidence intervals for the structural IRFs are computed based on the asymptotic normal distribution in Theorem 5 and the proposed consistent estimator of the covariance matrix. Our inferential results do not require knowledge about the cointegrating relationship or the (non)stationarity of a particular series.

Tables 1A–1C and 2A–2C report the finite-sample coverage rates of confidence intervals for DGP1 and DGP2, respectively. The nominal level is 95%. The number of simulation replications is 5,000. The notation “-” denotes that the corresponding contemporaneous IRF is normalized to be one. Under DGP1, the coverage rates of confidence intervals of the IRFs to a shock in \( \varepsilon_{jt} \) for \( j = 1, 2, 3 \) are summarized by Tables 1A, 1B, and 1C, respectively. The three rows associated with the same value of \( C_1 \) in Tables 1A–1C report the results for \( Y_{1t}, Y_{2t}, \) and \( Y_{3t} \), respectively.

The results in Tables 1A–1C show several patterns. First, the coverage rates are close to the nominal level for short horizons. Even in small samples with \( T = 200 \), for example, the effective coverage rates of the confidence intervals are always between 93.4% and 94.7% for horizon \( s = 0 \) and between 91.8% and 94.6% for horizon \( s = 2 \). Second, as the horizon increases, the effective coverage rates decrease. This is not surprising, because (1) the estimators \( \tilde{\Theta}_T \) based on the unrestricted OLS estimation are inconsistent for long horizons and for horizons \( s \) proportional to \( T \) its limiting distribution is also nonstandard in the presence of roots equal or close to unity (Phillips, 1998; Gospodinov, 2004; Pesavento and Rossi, 2007) and (2) the asymptotic normal approximation based on the Delta

\[4\text{In this paper, our asymptotic theory is based on the assumption that the horizon } s \text{ is a fixed number as } T \to \infty. \text{ Phillips (1998) studies the asymptotic properties of the IRFs under the alternative asymptotic setup, where } s \text{ could grow as fast as } T \text{ and the roots of the VAR model are unity or near unity.} \]

</table>

The method can perform poorly in small samples even in stationary VARs since the IRFs are highly nonlinear functions of the VAR coefficients (Kilian, 1999). Finally, the effective coverage rates are improving as the sample size increases, which confirms our asymptotic theory.
The main patterns in Tables 2A–2C are similar to those in Tables 1A–1C. Compared to the results under DGP1, the effective coverage rates in Tables 2A–2C tend to have larger downward biases, especially for shocks to $\epsilon_1$ and $\epsilon_2$ with $C_2 \in \{-2, -5, -10\}$. This could be caused by the fact that the system under

DGP2 has an additional root near unity in comparison to DGP1 for \( C_2 \in \{-2, -5, -10\} \). Under DGP2, the asymptotic distribution tends to require larger samples to generate good approximations. Additional simulation results (not included in
Table 2A–2C) confirm that the effective coverage rates are much closer to the nominal level under DGP2 for all IRFs with \( s \leq 12 \) when \( T \) increases to 5,000.

7. CONCLUSION

This paper shows that for proxy SVAR, standard asymptotic normal inference remains valid under a general form of nonstationarity in the VAR system. In the presence of stationary regressors, cointegration relationships, or more than one lag variables in the VAR, the estimation error from the nonstationary component is asymptotically negligible. The asymptotic variance of the IRF only depends on the stationary component, but a consistent covariance matrix estimator is available even without knowing which series are stationary. This robust and simple covariance matrix estimator is particularly appealing for practical applications.

The robustness result is rather general by allowing for local-to-unity processes. However, the theoretical result is not uniform over the entire parameter space of the roots of the autoregressive model, as those studied in (Mikusheva 2007, 2012) (2007, 2012), Andrews and Guggenberger (2010), and Phillips (2014). Establishing uniform inference for the SVAR-IV estimation is an interesting direction for future research.

APPENDIX

Below we first establish the link between (2.1) and (3.1) and show the representation in (3.3). Following (3.1), we can write

\[ \Delta Y_t = M(Y_{t-1} - c) + P\Psi(L)^{-1}e_t, \]  

where

\[ M = \begin{bmatrix} T^{-1}C & 0 & 0 \\ Q(I_{r_1} + T^{-1}C) & -I_{r_2} & 0 \\ 0 & 0 & -I_{r_3} \end{bmatrix} \]  

and

\[ P = \begin{bmatrix} I_{r_1} & 0 & 0 \\ Q & I_{r_2} & 0 \\ 0 & 0 & I_{r_3} \end{bmatrix}. \]  

Multiplying both sides of (A.1) by \( P\Psi(L)P^{-1} \), we obtain

\[ P\Psi(L)P^{-1}\Delta Y_t = P\Psi(L)P^{-1}M(Y_{t-1} - c) + Pe_t. \]  

Define \( \pi_1 = \Psi_1 + \cdots + \Psi_{p-1}, \pi_2 = \Psi_2 + \cdots + \Psi_{p-1}, \ldots, \) and \( \pi_{p-1} = \Psi_{p-1}. \) We can write

\[ \Psi(L) = 1 - \Psi_1L - \cdots - \Psi_{p-1}L^{p-1} \]
\[ = \Psi(1) + \pi_1(1 - L) + \pi_2(L - L^2) + \cdots + \pi_{p-1}(L^{p-2} - L^{p-1}). \]
Plugging (A.4) in (A.3), we obtain
\[
P^*[1 - \Psi_1 L - \cdots - \Psi_{p-1} L^{p-1}] P^{-1} \Delta Y_t
= \hat{P} [\hat{\Psi}(1) + \pi_1 (1 - L) + \pi_2 (L - L^2) + \cdots + \pi_{p-1} (L^{p-2} - L^{p-1})] P^{-1} M (Y_{t-1} - c) + P \varepsilon_t,
\] (A.5)
and a rearrangement gives
\[
\Delta Y_t = \hat{P} \Psi (1) P^{-1} M (Y_{t-1} - c) + P \varepsilon_t,
\] (A.6)
Define
\[
\Pi (L) = \Pi_1 + \Pi_2 L + \cdots + \Pi_{p-1} L^{p-2},
\] (A.7)
where \( \Pi_1 = P \Psi_1 P^{-1} + P \pi_1 P^{-1} M, \ldots, \Pi_{p-1} = P \Psi_{p-1} P^{-1} + P \pi_{p-1} P^{-1} M \). Then, we can write the model as
\[
\Delta Y_t = (P \Psi (1) P^{-1} M) (Y_{t-1} - c) + \Pi (L) \Delta Y_{t-1} + \eta_t, \text{ where } \eta_t = P \varepsilon_t.
\] (A.8)
Transforming (A.8) leads to the link between (2.1) and (3.1)
\[
Y_t = -P \Psi (1) P^{-1} M c + (P \Psi (1) P^{-1} M + I) Y_{t-1} + \Pi (L) \Delta Y_{t-1} + \eta_t,
\]
\[
Y_t = d + \Phi_1 Y_{t-1} + \cdots + \Phi_p Y_{t-p} + \eta_t,
\] (A.9)
where
\[
d = -P \Psi (1) P^{-1} M c,
\]
\[
\Phi_1 = (P \Psi (1) P^{-1} M + I) + \Pi_1,
\]
\[
\Phi_i = \Pi_i - \Pi_{i-1}, \text{ } i = 2, \ldots, p - 1,
\]
\[
\Phi_p = -\Pi_{p-1}.
\] (A.10)
Next, we derive (3.3). Using the definition of \( M \) and \( D_t \), (A.8) can be equivalently written as
\[
\Delta Y_t = A x_t + \eta_t
= A_1 (Y_{1,t-1} - c_1) + A_2 + A_3 D_t + \eta_t,
\] (A.11)
where
\[
A = [A_1 : A_2 : A_3], \text{ } x_t = [(Y_{1,t-1} - c_1)', 1, D_t]',
\]
\[
A_1 = P \Psi (1) P^{-1} \begin{bmatrix} T^{-1} C \\ 0 \end{bmatrix}, A_2 = \begin{bmatrix} 0 \\ 0 \end{bmatrix},
\]
\[
A_3 = \begin{bmatrix} P \Psi (1) P^{-1} \begin{bmatrix} 0 & 0 \\ -I_{r_2} & 0 \\ 0 & -I_{r_3} \end{bmatrix}, \Pi_1, \ldots, \Pi_{p-1} \end{bmatrix}.
\] (A.12)

**Proof of Lemma 1.** The results follow from Thm. 3.4 of Phillips and Solo (1992). The summability condition for the linear processes is satisfied by Assumption LP(i) and LP(ii).

Part (d) applies the CLT for second moments of linear processes as in Thm. 3.8 of Phillips and Solo (1992). The limiting covariance matrix of the asymptotic distribution is $\sum_{j=-\infty}^{\infty} \Omega_j$, where

$$\Omega_j = \begin{bmatrix} \Omega_{DD,j} & \Omega_{DZ,j} \\ \Omega_{ZD,j} & \Omega_{ZZ,j} \end{bmatrix},$$

$$\Omega_{DD,j} = \lim_{T \to \infty} E\left[ (\eta_t \otimes D_t) (\eta_{t-j} \otimes D_{t-j})' \right],$$

$$\Omega_{DZ,j} = \lim_{T \to \infty} E\left[ (\eta_t \otimes D_t) (\eta_{t-j} \otimes (Z_{t-j} - \mu Z) - \gamma)' \right],$$

$$\Omega_{ZD,j} = \lim_{T \to \infty} E\left[ (\eta_t \otimes (Z_t - \mu Z) - \gamma) (\eta_{t-j} \otimes D_{t-j})' \right],$$

$$\Omega_{ZZ,j} = E\left[ (\eta_t \otimes (Z_t - \mu Z) - \gamma)(\eta_{t-j} \otimes (Z_{t-j} - \mu Z) - \gamma)' \right].$$

(A.13)

Below, we show $\Omega_j = 0$ for $j \neq 0$ and $\Omega_0 = \Omega$.

Let $F_{t-1}$ denote the information set at $t-1$ generated by $\{\eta_{t-1}, Z_{t-1}, \eta_{t-2}, Z_{t-2}, \ldots\}$. Note that in the VAR model, $D_t$ is a function of $\eta_{t-1}$ and its lags. Because $\eta_t$ and $Z_t$ are both linear processes and the errors are i.i.d., by Assumption LP, we have (i) $E[\eta_t | F_{t-1}] = 0$, and $E[\eta_t \otimes Z_t | F_{t-1}] = \gamma_T$ and $E[\eta_t \eta_t' | F_{t-1}] = \Sigma_\eta$ are constant for any $T$, and (ii) $\lim_{T \to \infty} E[\eta_t \otimes Z_t | F_{t-1}] = \gamma$ and $E[\eta_t \eta_t' | F_{t-1}] = \Sigma_\eta$. Therefore, all the autocovariances $\Omega_j$ with $j \neq 0$ are zero by the law of iterated expectations (LIE).

For $j = 0$, we show $\Omega_0 = \Omega$, i.e., the matrix has the Kronecker product structure. To this end, note that

$$\Omega_{DD,0} = E\left[ (\eta_t \eta_t') \otimes (D_t D_t') \right] = E\left[ E(\eta_t \eta_t' | F_{t-1}) \otimes (D_t D_t') \right] = \Sigma_\eta \otimes \Gamma_{DD},$$

(A.14)

by LIE and $E(\eta_t \eta_t' | F_{t-1}) = \Sigma_\eta$. Next,

$$\Omega_{DZ,0} = \lim_{T \to \infty} E\left[ (\eta_t \eta_t') \otimes D_t Z_t' \right] = \lim_{T \to \infty} E\left[ E(\eta_t \eta_t' | F_{t-1}, v_t) \otimes (D_t Z_t') \right] = \Sigma_\eta \otimes \Gamma_{DZ},$$

(A.15)

because $\eta_t = Pe_t$ and $e_t$ is homoskedastic conditional on $F_{t-1}$ and $v_t$. We have $\Omega_{DZ,0} = \Omega_{DZ,0}'$. Finally,

$$\Omega_{ZZ,0} = \lim_{T \to \infty} E\left[ \eta_t \eta_t' \otimes (Z_t - \mu Z) (Z_t - \mu Z)' \right] - \gamma \gamma'$$

$$= \lim_{T \to \infty} E\left[ E(\eta_t \eta_t' | F_{t-1}, v_t) \otimes (Z_t - \mu Z) (Z_t - \mu Z)' \right] - \gamma \gamma'$$

$$= \Sigma_\eta \otimes \Gamma_{ZZ} - \gamma \gamma'.$$

(A.16)
Proof of Theorem 1. Applying the formula for $\hat{\theta}$ in (2.6), we have

$$T^{1/2} (\hat{\theta} - \theta) = (A_T W_T A_T')^{-1} A_T W_T B,$$

where

$$A_T = I_{r-1} \otimes \left( \sum_{t=1}^T \eta_{t-1} Z_t \right)$$

and

$$B = T^{-1/2} \left[ \sum_{t=1}^T (\eta_{t-1} \otimes Z_t) - \left( I_{r-1} \otimes \sum_{t=1}^T Z_t \eta_{t-1} \right) \theta \right]$$

$$= T^{-1/2} \sum_{t=1}^T (\eta_{t-1} - \theta \eta_{t-1}) \otimes Z_t$$

$$= T^{-1/2} \sum_{t=1}^T (S_{\theta} \eta_t) \otimes (Z_t - \mu_Z). \quad (A.17)$$

where the second last equality uses $(I_{r-1} \otimes Z_t \eta_{t-1}) \theta = \theta \eta_{t-1} \otimes Z_t$ because $\eta_{t-1}$ is a scalar, and the last equality holds because $S_{\theta} \eta_t = \eta_{t-1} - \theta \eta_{t-1}$ and the fitted model (2.1) includes an intercept and thus the OLS residuals have a sample mean equal to 0.

To study the asymptotic distribution of $B$, note that

$$B = B_1 + B_2,$$

where

$$B_1 = T^{-1/2} \sum_{t=1}^T (S_{\theta} \eta_t) \otimes (Z_t - \mu_Z).$$

$$B_2 = T^{-1/2} \sum_{t=1}^T \left[ S_{\theta} (\eta_t - \eta_t) \right] \otimes (Z_t - \mu_Z). \quad (A.18)$$

In $B_1$, note that $E\left[ S_{\theta} \eta_t \otimes (Z_t - \mu_Z) \right] = 0$ following the moment condition for the estimation of $\theta$ and $E[\eta_t] = 0$. Then, it follows from Lemma 2(d) that

$$B_1 = T^{-1/2} \sum_{t=1}^T \left\{ \left( S_{\theta} \eta_t \right) \otimes (Z_t - \mu_Z) - E\left[ \left( S_{\theta} \eta_t \right) \otimes (Z_t - \mu_Z) \right] \right\}$$

$$= (S_{\theta} \otimes I_k) \left\{ T^{-1/2} \sum_{t=1}^T \eta_t \otimes (Z_t - \mu_Z) - E[\eta_t \otimes (Z_t - \mu_Z)] \right\}$$

$$\rightarrow_d (S_{\theta} \otimes I_k) \xi Z. \quad (A.19)$$

Let $X$ denote the matrix of $x_t$ and $\eta$ denote the vector of $\eta_t$. To study the distribution of $B_2$, note that

$$B_2 = T^{-1/2} \sum_{t=1}^T \left[ S_{\theta} (\eta_t - \eta_t) \right] \otimes (Z_t - \mu_Z)$$

$$= T^{-1/2} \sum_{t=1}^T \left[ S_{\theta} \eta_t X(X'X)^{-1} x_t \right] \otimes (Z_t - \mu_Z)$$
where the second equality follows from the least-squares estimation of \( \eta_t \), \( \Upsilon_T \) in the third equality is defined in (3.9), the fourth equality uses \( \text{vec}(AXB) = (B' \otimes A)\text{vec}(X) \) for column vectorization, and \( \ell_T \) denotes the \((T - p) \times 1\) vector of ones. In the last equality above, the first term satisfies

\[
T^{-1}(Z - \ell_T \mu'_T)'XY_T^{-1}
\]

\[
= \left[ T^{-\frac{3}{2}} \sum_{t=1}^{T} (Z_t - \mu_Z)Y_t' : T^{-1} \sum_{t=1}^{T} (Z_t - \mu_Z) : T^{-1} \sum_{t=1}^{T} (Z_t - \mu_Z)D_t \right]
\]

\[
\to p\left[ 0_{k \times (r_1+1)}, \Gamma_D'Z \right]
\]  

by Lemma 2(b). Using the block diagonality of \( V \) in Lemma 2(a), we can reduce A.20 to

\[
-\text{vec}[\Gamma_D'Z \cdot \Gamma_D D^{-1} \cdot (T^{-\frac{1}{2}} \sum_{t=1}^{T} D_t \eta'_t)S_{\theta}'] + o_p(1)
\]

\[
= -(S_{\theta} \otimes [\Gamma_D' \cdot \Gamma_D D^{-1}]) \text{vec}[T^{-\frac{1}{2}} \sum_{t=1}^{T} D_t \eta'_t] + o_p(1)
\]

\[
= -(S_{\theta} \otimes [\Gamma_D' \cdot \Gamma_D D^{-1}]) T^{-\frac{1}{2}} \sum_{t=1}^{T} \eta_t \otimes D_t + o_p(1)
\]

\[
\to_d - (S_{\theta} \otimes K) \xi_D,
\]  

where both equalities use \( \text{vec}(AXB) = (B' \otimes A)\text{vec}(X) \) for column vectorization and the convergence follows from Lemma 2(d).

To derive the limit of \( A_T \), we have

\[
T^{-1} \sum_{t=1}^{T} \tilde{\eta}_{i,t}Z'_t = T^{-1} \sum_{t=1}^{T} \eta_{i,t}Z'_t + T^{-1} \sum_{t=1}^{T} (\tilde{\eta}_{i,t} - \eta_{i,t})Z'_t
\]

\[
\to_p E(\eta_{i,t}Z'_t),
\]

where \( T^{-1} \sum_{t=1}^{T} (\tilde{\eta}_{i,t} - \eta_{i,t})Z'_t \to_p 0 \) follows from arguments similar to those used to study \( B_2 \). Hence,

\[
A_T \to_p A = I_{r-1} \otimes E(\eta_{i,t}Z'_t).
\]

Under Assumption R1, \( V \) is a full rank matrix and thus is invertible. The optimal choice of the weighting matrix follows from standard arguments for GMM estimators.
Proof of Theorem 2. Because the $s$-step-ahead VMA coefficient matrix is given by $\Theta_s = M^T F^s M$, we have
\[
d\Theta_s = \sum_{i=0}^{s-1} M^T F^{s-1-i} d F^i M
= \sum_{i=0}^{s-1} (M^T F^{s-1-i} [d \Phi_1 \cdots d \Phi_p] F^i M
= \sum_{i=0}^{s-1} \Theta_{s-1-i} [d \Phi_1 \cdots d \Phi_p] F^i M,
= \sum_{i=0}^{s-1} \Theta_{s-1-i} [d d \Phi_1 \cdots d \Phi_p] S_2^i F^i M
\tag{A.25}
\]
and
\[
vec(d\Theta_s') = \sum_{i=0}^{s-1} \left[ \Theta_{s-1-i} \otimes (M' F^i) \right] vec(S_2 [d d \Phi_1 \cdots d \Phi_p]'),
\tag{A.26}
\]
where $S_2 = [0_{p \times 1}: I_{rp}]$ is the selector matrix that removes the first row.

Recall that $L$ is defined in (3.15) such that
\[
x_t = \begin{bmatrix}
Y_{1,t-1} - c_1 \\
1
Y_{2,t-1} - c_2 - Q(Y_{1,t-1} - c_1)
Y_{3,t-1} - c_3
\Delta Y_{t-1}
\vdots
\Delta Y_{t-p+1}
\end{bmatrix}
= L \begin{bmatrix}
1
Y_{t-1}
Y_{t-2}
\vdots
Y_{t-p}
\end{bmatrix}
= LX_t,
\tag{A.27}
\]

which is a transformation between regressors in the model in (2.1) and the regressors in its equivalent representation in (3.3). For the OLS estimators, this implies that the OLS regression coefficients of the model in (2.1) and the OLS coefficients of that in (3.3) satisfy
\[
\begin{bmatrix}
\tilde{d} : \tilde{\Phi}_1 - I_r : \tilde{\Phi}_2, \ldots, \tilde{\Phi}_p
\end{bmatrix} = \begin{bmatrix}
\tilde{A}_1 : \tilde{A}_2 : \tilde{A}_3
\end{bmatrix} L.
\tag{A.28}
\]

It follows from (A.26) and (A.28) that
\[
T^{\frac{1}{2}} vec(\tilde{\Theta}_s' - \Theta_s')
= R vec \left( S_2 L'T^{\frac{1}{2}} \left( \sum_{t=p+1}^{T} x_t x_t' \right)^{-1} \sum_{t=p+1}^{T} x_t \eta_t \right) + o_p(1)
= R vec \left( S_2 L'T^{\frac{1}{2}} \left( \sum_{t=p+1}^{T} \gamma_T^{-1} x_t x_t' \gamma_T^{-1} \right)^{-1} \gamma_T^{-1} T^{-\frac{1}{2}} \sum_{t=p+1}^{T} x_t \eta_t \right) + o_p(1).
\tag{A.29}
\]

Because $V$ is block-diagonal consisting of the $(r_1+1) \times (r_1+1)$ upper-left submatrix and the $(rp-r_1) \times (rp-r_1)$ lower-right submatrix, $\gamma_T^{-1} = \text{diag}(0_{r_1 \times r_1}, I_{rp-r_1+1}) + o(1)$, and
the \((r_1 + 1)\)st column of \(S_2 L'\) consists of zeros. Thus,
\[
S_2 L' Y_T^{-1} (T^{-1} \sum_{l=1}^{T} \gamma_{T}^{-1} x_l y_l')^{-1} Y_T^{-1} T^{-\frac{1}{2}} \sum_{l=1}^{T} x_l y_l' \]
\[
= \overline{\Gamma}_{DD}^{-1} T^{-\frac{1}{2}} \sum_{l=1}^{T} D_l y_l' + o_p(1),
\]

(A.30)

where \(\overline{\Gamma}\) is the \(rp \times (rp - r_1)\) lower-right submatrix of \(L'\) defined in (3.17) and it has full rank by construction.

Combining (A.29) and (A.30) yields
\[
T^{\frac{1}{2}} \text{vec}(\Theta_{s} - \Theta_{s}') = \mathcal{R}[I_r \otimes (\overline{\Gamma}_{DD}^{-1})] \text{vec}(T^{-\frac{1}{2}} \sum_{l=p+1}^{T} D_l y_l') + o_p(1)
\]
\[
\rightarrow_d \mathcal{R}[I_r \otimes \mathcal{J}] \xi_D.
\]

(A.31)

Proof of Theorem 3. For \(s \geq 1\),
\[
T^{\frac{1}{2}} (\hat{\beta}_s - \beta_s) = \Theta_{s} T^{\frac{1}{2}} (\hat{h} - h) + T^{\frac{1}{2}} (\Theta_{s} - \Theta_{s}) h
\]
\[
= \Theta_{s} T^{\frac{1}{2}} (\hat{h} - h) + (I_r \otimes h') T^{\frac{1}{2}} \text{vec}(\Theta_{s} - \Theta_{s}').
\]

(A.32)

The first term in (A.32) can be rewritten as
\[
\Theta_{s} T^{\frac{1}{2}} (\hat{h} - h) = \Theta_{s} T^{\frac{1}{2}} S_i \begin{bmatrix} 0 \\ \hat{\theta} - \theta \end{bmatrix} + o_p(1)
\]
\[
= \Theta_{s} S_i \begin{bmatrix} 0 \\ \hat{\theta} - \theta \end{bmatrix} + o_p(1)
\]
\[
\rightarrow_d \Theta_{s} S_i \begin{bmatrix} \xi_D \\ \xi_Z \end{bmatrix},
\]

(A.33)

where \(S_i\) denotes the last \(r - 1\) columns of \(S_i\), and the convergence follows from Theorem 1.

By Theorem 2, the second term in (A.32) can be rewritten as
\[
(I_r \otimes h') T^{\frac{1}{2}} \text{vec}(\Theta_{s} - \Theta_{s}') \rightarrow_d (I_r \otimes \mathcal{J}) \mathcal{R}[I_r \otimes \mathcal{J}] \xi_D.
\]

(A.34)

Thus, combining (A.33) and (A.34) yields Theorem 3.

Proof of Lemma 3. The estimator \(\hat{\mathcal{K}}\) satisfies
\[
\hat{\mathcal{K}} L^{-1} \gamma_T
\]
\[
= \hat{\Gamma}_{ZX} \hat{\Gamma}_{XX} L^{-1} \gamma_T
\]
\[
= \left( \sum_{t=p+1}^{T} (Z_t - \bar{Z}_T) x_t y_t^{-1} \right) \left( \sum_{t=p+1}^{T} \gamma_T^{-1} x_t y_t^{-1} \right)^{-1}
\]
\[
\left( T^{-1} \sum_{t=p+1}^{T} (Z_t - \mu_Z) \gamma_T^{-1} \right) \left( T^{-1} \sum_{t=p+1}^{T} \gamma_T^{-1} x_t' \gamma_T^{-1} \right)^{-1} + o_p(1)
\]

\[
\to p [0_{k \times (r_1+1)} : \Gamma_D' \Gamma_D^{-1}] = [0_{k \times (r_1+1)} : \mathcal{K}],
\]

where the first equality holds by definition, the second equality follows from \(x_t = \mathbb{L}X_t\) by (A.27), and the third equality uses

\[
\left[ T^{-\frac{1}{2}} \sum_{t=1}^{T} (\hat{Z}_T - \mu_Z) \gamma_T^{* t-1} : T^{-1} \sum_{t=1}^{T} (\hat{Z}_T - \mu_Z) : T^{-1} \sum_{t=1}^{T} (\hat{Z}_T - \mu_Z) D_t \right] = o_p(1),
\]

which further follows from Lemma 2(b) and 2(c), and the convergence in probability follows from Lemma 2(a) and 2(b), in particular the block-diagonal structure of \(V\) in Lemma 2(a).

The estimator \(\hat{J}\) satisfies that

\[
\hat{J} \mathbb{L}^{-1} \gamma_T
\]

\[
= S_2 \hat{\Gamma}_X^{-1} \mathbb{L}^{-1} \gamma_T
\]

\[
= S_2 \hat{L}' \gamma_T^{-1} \left( T^{-1} \sum_{t=1}^{T} \gamma_T^{-1} x_t' \gamma_T^{-1} \right)^{-1}
\]

\[
\to p [0_{r_\theta \times (r_1+1)} : \mathbb{E} \Gamma_D^{-1}] = [0_{r_\theta \times (r_1+1)} : \mathcal{J}],
\]

where the first equality holds by definition, the second equality uses \(x_t = \mathbb{L}X_t\), and the convergence in probability follows from Lemma 2(a), because \(V\) is block-diagonal, the first \(r_1\) diagonal elements of \(\gamma_T^{-1}\) are \(o(1)\), the \((r_1+1)\)th column of \(S_2 \hat{L}'\) is 0, and the remaining columns of \(S_2 \hat{L}'\) are denoted by \(\mathbb{L}\) by definition.

Given the definition of \(\mathbb{P}\), (A.35), (A.37), the consistency of \(\hat{\theta}\), and the continuous mapping theorem give

\[
\hat{G}_{13} \mathbb{P} \to_p \Theta_3 \mathbb{S}_1 (AW' A')^{-1} AW[-S_\theta \otimes [0_{k \times (r_1+1)} : \mathcal{K}] : S_\theta \otimes I_k],
\]

\[
\hat{G}_{23} \mathbb{P} \to_p [ (I_r \otimes h') \mathcal{R} (I_r \otimes [0_{r_\theta \times (r_1+1)} : \mathcal{J}] : 0_{r \times r_\theta}]\]

\(\blacksquare\)

**Proof of Lemma 4.** Note that

\[
P^{-1} \hat{\Omega} P^{-1'} = 
\begin{bmatrix}
\hat{\Sigma}_\eta \otimes \left[ T^{-1} \sum_{t=1}^{T} \gamma_T^{-1} x_t' \gamma_T^{-1} \right] & \hat{\Sigma}_\eta \otimes \left[ T^{-1} \sum_{t=1}^{T} \gamma_T^{-1} x_t (Z_t - \hat{Z}_T)' \right] \\
\hat{\Sigma}_\eta \otimes \left[ T^{-1} \sum_{t=1}^{T} (Z_t - \hat{Z}_T) x_t' \gamma_T^{-1} \right] & \hat{\Sigma}_\eta \otimes \left[ T^{-1} \sum_{t=1}^{T} (Z_t - \hat{Z}_T)(Z_t - \hat{Z}_T)' \right] - \tilde{\gamma} \tilde{\gamma}'
\end{bmatrix}
\]

(A.40)
where all $X_t$ is transformed to $Y_T^{-1}x_t$ and $Z_t$. Let $\hat{\beta}_T = (\sum_{t=1}^{T}x_t'x_t')^{-1}(\sum_{t=1}^{T}x_t Y_t')$ denote the OLS regression coefficients that yield the residual $\tilde{\eta}_t$. Note that

$$\Delta = -Y_T(\hat{\beta}_T - \beta) = -\left(T^{-1}\sum_{t=1}^{T}Y_T^{-1}x_t\hat{\gamma}_T^{-1}\right)^{-1}T^{-1}\sum_{t=1}^{T}Y_T^{-1}x_t\eta_t' = Op(T^{-\frac{1}{2}}) \tag{A.41}$$

by Lemma 2(a), 2(c), and 2(d). To investigate $\hat{\Sigma}_\eta$, note that

$$\tilde{\eta}_t\tilde{\eta}_t' = (\eta_t - (\hat{\beta}_T - \beta)'x_t)(\eta_t - (\hat{\beta}_T - \beta)'x_t)' = \eta_t\eta_t' - \Delta'\gamma_T^{-1}x_t\tilde{\eta}_t' - \eta_t\tilde{\gamma}_T^{-1}\Delta' + \Delta'\gamma_T^{-1}x_t\tilde{\gamma}_T^{-1}\Delta'. \tag{A.42}$$

Applying (A.42) to $\hat{\Sigma}_\eta$, we obtain

$$\hat{\Sigma}_\eta = \frac{1}{T}\sum_{t=1}^{T}\eta_t\eta_t' - \Delta'\frac{1}{T}\sum_{t=1}^{T}\gamma_T^{-1}x_t\eta_t' - \frac{1}{T}\sum_{t=1}^{T}\eta_t\tilde{\gamma}_T^{-1}\Delta' - \Delta'\frac{1}{T}\sum_{t=1}^{T}\tilde{\gamma}_T^{-1}x_t\eta_t' \Delta \tag{A.43}$$

by Lemma 2(a), 2(c), and 2(d) and (A.41).

To study the upper-right submatrix of (A.40), note that

$$\frac{1}{T}\sum_{t=1}^{T}\gamma_T^{-1}x_t(Z_t - \bar{Z}_T)' \rightarrow p \left[0_{k \times (r_1 + 1)}, \Gamma_{DZ} \right]' \tag{A.44}$$

following (A.21) and Lemma 2.

Finally, the first moment satisfies

$$\hat{\gamma} - \gamma = \frac{1}{T}\sum_{t=1}^{T}\tilde{\eta}_t \otimes Z_t - \gamma = \left(\frac{1}{T}\sum_{t=1}^{T}\eta_t \otimes Z_t - \gamma\right) - \Delta'\left(\frac{1}{T}\sum_{t=1}^{T}\gamma_T^{-1}x_t \otimes Z_t\right) = Op(T^{-\frac{1}{2}}) \tag{A.45}$$

by Lemma 2(d) and (A.41).

The desirable result follows from (A.40), (A.43), (A.44), (A.45), and Lemma 2(a) and 2(b).

**Proof of Theorem 4.** Combining Lemmas 3 and 4, the zero matrices in the limit of $(\hat{G}_1 + \hat{G}_2)\hat{P}$ and its transpose reduce $\hat{V}$ and $\gamma_{\Delta Z}$ in the limit of $\hat{P}^{-1}\hat{\Sigma}\hat{P}^{-1}'$ to their submatrices $\Gamma_{D\Delta}$ and $\Gamma_{DZ}$, respectively. This removes all nondeterministic elements in $\hat{V}$ and $\gamma_{\Delta Z}$, and the consistency result follows immediately.

**Proof of Theorem 5.** Part (a) follows from the arguments used for Theorem 4. Parts (b) and (c) follow from Theorems 1 and 3.
