Abstract

Porous transition metal dichalcogenides (TMDs) are promising candidates for a variety of catalytic, purification, and energy storage applications. Despite recent advances, current fabrication techniques face issues concerning scalability and control over sample porosity. By utilizing water-assisted laser irradiation, we present here a new method for the fabrication of micron-scale, atomically-thin nanoporous tungsten disulfide (WS₂) membranes. The electronic and physical structures of the porous membranes are characterized with photoluminescence (PL) spectroscopy and aberration-corrected scanning transmission electron microscopy (AC-STEM), respectively. With increasing laser irradiation dose, we observe a decay of PL signal, and a relative increase in the trion contribution compared to that of the neutral exciton, suggesting defect-related n-type doping and degradation of the membrane. AC-STEM images show the nucleation of tungsten oxide islands on the membrane, and the formation of triangular defect clusters containing a combination of nanopores and oxide-filled regions, providing insight at the

a Electronic mail: drndic@physics.upenn.edu
atomic level into the photo-oxidation process in TMDs. A linear dependence of the nanoporous area percentage on the laser irradiation dose over the range of $10^2$-10$^5$ W/cm$^2$ is observed. The methods proposed here pave the way for the scalable production of nanoporous membranes through the laser-induced photo-oxidation of WS$_2$ and other transition metal dichalcogenides.

Introduction

Among the family of 2D materials, transition metal dichalcogenides (TMDs) have attracted a lot of attention as potential candidates for photodetection, purification, energy storage, and catalysis applications. Building upon the successful paradigm established by porous carbide-derived carbon (CDC) compounds in the latter application, porous TMDs and TMD-CDC hybrids have been heavily explored as possible electrocatalysts, photocatalysts, and purification catalysts. Despite their favorable performance, current fabrication techniques for porous TMDs based on solution-phase synthesis and sol-gel methods are primarily limited to relatively slow and energy-intensive recipes that either offer little to no tunability over sample porosity or fail to produce pore sizes below ~ 100 nm and fully utilize the 2D characteristics of the material. Similarly, recently-reported methods for fabricating nanoporous molybdenum disulfide (MoS₂) based on ion beam patterning and bottom-up molecular beam epitaxy (MBE) seem promising but require a number of time-consuming processes, often under high-vacuum conditions that raise concerns over scalability. This necessitates the development of a process for the fabrication of TMDs with tunable porosity that is both rapid and scalable.

Owing to their direct semiconducting band gap and strong photoluminescence (PL) signature, monolayer TMDs have been probed for various optoelectronic applications such as phototransistors, light-emitting diodes, and solar cells. Due to their strong optical absorption, the controlled layer-by-layer thinning of MoS₂ as well as the patterning of micron-scale holes in tungsten disulfide (WS₂) have also been achieved through laser-induced ablation. While the basal plane of monolayer flakes is known to be highly stable, intrinsic defects and edge sites have been shown to provide nucleation sites for this degradation process, which is accelerated in the presence of water. These laser-induced defects,
however, have not been observed at the atomic level and their study can provide more insight into the degradation process.

Here, we demonstrate the controlled water-assisted photo-oxidation of pristine monolayer WS$_2$ membranes as a new method for producing nanopores and nanoporous TMDs with tunable porosity on the time scale of a few seconds. We analyze changes in the material’s electronic structure through PL spectroscopy in addition to quantitatively and qualitatively characterizing the nature of the resulting porous structure using transmission electron microscopy (TEM) and electron energy loss spectroscopy (EELS).

**Methods**

Monolayer triangular WS$_2$ flakes are grown using a chemical vapor deposition (CVD) technique similar to that demonstrated by Kim *et al.* (2016). We note here that the use of monolayer WS$_2$ arises from a combination of its highly-developed CVD growth techniques and exceptional room temperature PL properties in comparison to other TMDs. Figure 1a shows an optical image of resulting triangular flakes on a 150 nm-thick SiO$_2$ substrate. The monolayer nature of the flakes was confirmed via Raman spectroscopy (Figure 1b) with an excitation wavelength of 532 nm. The Raman spectrum consists of the four primary modes – first-order in-plane acoustic mode, $LA(M)$ (175 cm$^{-1}$), second-order in-plane acoustic mode, $2LA(M)$ (353 cm$^{-1}$), first-order in-plane optical mode, $E’(\Gamma)$ (357 cm$^{-1}$), and first-order out-of-plane optical mode, $A_1’$ (419 cm$^{-1}$) – and their derivative peaks. The higher relative intensity of the $2LA(M)$ to $A_1’$ mode and the absence of a prominent peak at ~ 310 cm$^{-1}$ suggests the monolayer quality of the flake. However, to further verify that our flakes are in fact monolayer, we obtain PL spectra, as described later in the text. The flakes are transferred onto perforated carbon grids (perforation diameter ~ 2.5 $\mu$m) using a standard PMMA-based KOH wet etch technique. A scanning...
electron microscope (SEM) image of a WS2 flake suspended over multiple holes is shown in Figure 1c. Figure 1d shows a high-angle annular dark-field (HAADF) lattice image of a suspended region that was obtained in an aberration-corrected scanning transmission electron microscope (AC-STEM) along with (Figure 1d inset) a selected area electron diffraction (SAED) pattern.

Samples were irradiated with a laser using a custom-built illumination setup, as shown in Figure 2a. Suspended WS2 membranes were immersed in deionized (DI) water and located optically using a 60X water immersion objective lens and an integrated CMOS camera. A green laser ($\lambda = 532$ nm, $P = 5$ mW) was then focused on selected membranes for an irradiation time ($t \sim 5$ seconds with different laser power densities (i.e., irradiation doses) modulated using a step variable neutral density (ND) filter. It should be noted here that no rastering of the laser was performed in this study. DI water provides the necessary oxidizing environment for the photo-oxidation reaction.21–23 Due to its higher refractive index in comparison to air, DI water also allows for a higher numerical aperture (NA) objective lens (spot size = 540 nm), which localizes the effects of photo-oxidation, thus making it easier to analyze the entire affected area within the limited field of view of the TEM. It should be noted that use of the dichroic mirror in the setup is required for image capture by the camera and reduces the laser power reaching the sample. As a result, laser irradiation dose calculations were performed using power values measured at the sample stage using a power meter. In our experiments, the laser irradiation dose ($D$) was varied from $\sim 10^2$ to $10^5$ W/cm², which is lower than the dose required for laser-induced thermal ablation of TMDs (MoS2).19 Multiple membranes ($n \geq 3$) were irradiated for each dose (Figure S1). Immediately after irradiation, samples were annealed at 250°C for 90 minutes in a Ar/H₂ environment to reduce hydrocarbon contamination during SEM, STEM, and PL analysis. Based on HAADF STEM images (Figure S6) and previous reports of annealed nanopores and
nanoporous membranes,\textsuperscript{4,20} annealing at these temperatures, well below the decomposition temperatures of TMDs (\textasciitilde 600-700\textdegree C),\textsuperscript{30} does not change the size of defects. A comparison of SEM images of the samples obtained before and after irradiation revealed varying degrees of photo-degradation of the membranes dependent on laser dose (Figure 2b) and served as a quick check before further spectroscopic and AC-STEM analysis were performed. Control experiments in air did not show the formation or expansion of defects in membranes upon laser irradiation, regardless of the presence of initial defects, even for irradiation times, \( t > 4 \) minutes and doses, \( D \sim 10^5 \text{ W/cm}^2 \) (Figure S2), strongly suggesting the need of a conducive oxidizing environment and illumination condition for defect expansion at the given dose.\textsuperscript{20,21}

**Results and Discussion**

To study the effect of laser-induced damage on suspended membranes, we characterize changes in the electronic and physical structure of WS\(_2\) using a combination of PL spectroscopy and AC-STEM imaging, respectively. Figure 3a shows the PL spectrum of a pristine suspended monolayer WS\(_2\) membrane. An excitation wavelength of 532 nm (spot size = 940 nm) and incident laser power of \( \sim 50 \mu \text{W} \) were used to prevent unwanted laser-induced degradation during measurements.\textsuperscript{19} A strong PL signal is obtained near the direct bandgap value of WS\(_2\) (\( \sim 2.05 \) eV), which verifies the monolayer quality of our flake.\textsuperscript{25} The spectrum is curve-fitted to three Lorentzian components – namely the neutral exciton (\( X_0 \)), the trion (\( X_T \)) and the defect-related (\( X_D \)) peaks, which are centered around \( \sim 2.02, 1.99 \) and 1.88 eV, respectively.\textsuperscript{20,31} The average spectral weight percentages of the \( X_0, X_T \) and \( X_D \) peaks were calculated from multiple pristine samples and found to be \( \sim 74\% , 25\% \) and 1\%, respectively.

Figure 3b shows the normalized PL spectra of the WS\(_2\) membranes before and after laser irradiation at different doses. The before spectra were taken on pristine WS\(_2\) membranes in air
prior to immersion and laser irradiation in DI water. The spectra indicated as after were also obtained in air, but after the experiment was completed, i.e., the membranes were immersed in DI water and exposed to laser irradiation. For the non-laser irradiated case (P = 0 W/cm²), samples were immersed in DI water but not exposed to any laser light. The PL peak shift and intensity changes before and after irradiation are plotted for several irradiation doses in Figure 3c. The spectral weight percentages of post-irradiation spectra were also calculated and are plotted in Figure 3d. It was observed that the PL peak redshifts for all irradiation doses and the shift increases with increasing dose, while the PL intensity decays with higher laser irradiation doses. The PL shift was calculated at different laser doses averaged over > 5 samples for each dose. Specifically, the PL redshift was found to be 5.6 ± 5.0 meV and 5.6 ± 3.6 meV for P = 0 W/cm² and P = 4.80 x 10³ W/cm², respectively, which are both smaller than the PL shift for P = 6.33 x 10⁴ W/cm² (10.6 ± 6.2 meV). We note that the non-zero PL redshift for P = 0 W/cm² is likely due to the formation of a small number of defects due to water exposure under ambient light, which we verify later using AC-STEM analysis (Figure 4a). Similar averaged PL shifts for P = 0 W/cm² and P = 4.80 x 10³ W/cm² means that PL shifts are not sensitive to the difference in the density of defects in non-irradiated samples after water exposure and samples irradiated at low doses (< 10⁴ W/cm²) (Figures 4a-b and S1). Furthermore, the relatively large error bars in the PL shift also imply that the variation in the density of defects at low doses across different samples is large enough such that the averaged PL shifts are indistinguishable between zero-dose and low-dose (< 10⁴ W/cm²) irradiated samples. As the irradiation dose increases (P = 6.33 x 10⁴ W/cm²), the defect density increases as expected, leading to a larger PL redshift. For doses from 0 (pristine) to 10⁴ W/cm², the X₇ contribution increases while the X₀ peak contribution diminishes. While both peaks decay with increasing laser irradiation dose, a conversion from neutral to charged exciton emission (n-type doping) is also seen via a redshift and broadening of
the PL spectra. We note that this is opposite to what was observed in plasma-irradiated WS\textsubscript{2} in which the $X_T$ contribution decreased.$^{31}$ The $X_D$ contribution remains negligible (< 10%) for all laser doses, suggesting a different kind of defect formation compared to electron beam-induced or plasma-induced defects.$^{20,31}$ For higher doses ($D \sim 10^5 \text{ W/cm}^2$), the majority of the membranes were seen to break (Figures 2b, 4d and S1) and the PL spectra obtained after irradiation are extremely weak compared to those obtained before irradiation (> 800-fold decay). The direct dependence of laser-induced effects on the laser power we observe (decay of $X_0$ and $X_T$) is similar to what has been observed for WSe\textsubscript{2} $^{22}$ but contrary to the power independence in the case of MoS\textsubscript{2}.$^{21}$

Defects, substrate effects and chemical doping are known to induce n-type doping of TMDs.$^{32–34}$ We can rule out any substrate effects for our case as we are analyzing only suspended membranes. Since membranes are annealed after laser irradiation, we also preclude any doping due to O\textsubscript{2}/H\textsubscript{2}O adsorption.$^{35,36}$ While we do observe oxide formation on our flakes due to DI water exposure (from our AC-STEM analysis as shown in Figures 4, 5 and S1), we do not see a net PL blueshift or $X_0$ peak contribution enhancement expected from oxide-induced p-type doping, shown previously by several studies.$^{37–39}$ Defect-induced doping is also known to reduce exciton lifetime in TMDs which can in turn decrease the PL intensity.$^{40}$ This suggests that while laser-induced defects degrade the membrane, they also introduce defect-induced n-type doping, which is the dominant doping mechanism, in the membrane. It should be noted that the relatively large error bars (~60-70%) for dose = $6.33 \times 10^4$ W/cm\textsuperscript{2} in Figure 3c-d indicate a wider distribution in defect sizes and large defect density in the regime of higher irradiation doses, which we confirm later using AC-STEM analysis (Figure 5).

Bulk properties of laser-irradiated TMD flakes have been studied previously using spectroscopy, optical microscopy and atomic force microscopy.$^{21–23,41,42}$ While monolayer TMDs
are known to be more resistant to laser degradation than their few-layer counterparts, the former was still seen to undergo decay, which was attributed to the presence of intrinsic lattice defects in the monolayer basal plane.\textsuperscript{21,22} Indeed, the introduction of defects in the form of nanopores in suspended monolayers and subsequent laser irradiation was demonstrated to expand the nanopore at a controllable rate as a function of laser dose.\textsuperscript{20} However, to our knowledge, the effects of laser irradiation on intact monolayers and the fabrication of laser-induced defects have not yet been explored at the atomic level. A better understanding of the laser-induced defect creation would allow for not only better control of the process for scalable applications but also the manipulation of the properties of TMDs.

To observe the effects of laser irradiation on our WS\textsubscript{2} membranes, we characterize the exposed samples using AC-STEM, which enables structural observations of micron-scale membranes as well as atomic-scale damage. Representative membranes for laser irradiation doses of 0, 4.80x10\textsuperscript{3}, 6.33x10\textsuperscript{4}, and 6.31x10\textsuperscript{5} W/cm\textsuperscript{2} are shown in Figure 4a-d, with corresponding AC-STEM images of a single defect outlined in yellow shown underneath. We note that the term defect is taken here to mean any region of the membrane which does not contain an intact WS\textsubscript{2} lattice. All the membranes shown were part of the same carbon grid and, as a result, were subjected to the same pre- and post-processing procedures. Regardless of laser irradiation dose, all flakes demonstrate the formation of white islands visible in the TEM images not present initially (Figure S5), which, as discussed later, were determined to be tungsten oxide (WO\textsubscript{3}) through EELS analysis (Figure 5e). Most of the pristine ($D = 0$ W/cm\textsuperscript{2}) samples are intact with a few photo-induced triangular defects over a suspended area of \hbox{$\sim 5$ \mu m\textsuperscript{2}} (Figure S1). This suggests that tungsten oxide islands and a small number of defects form even during water exposure under ambient light. With increasing laser irradiation dose, the observed defects have larger areas with a noticeably higher density. At the highest dose ($D \sim 10^5$ W/cm\textsuperscript{2}), the defected
area is large enough such that the membrane is structurally weakened and therefore collapses. Two such membranes irradiated at 6.31x10^5 W/cm², one of which did not collapse, are shown in Figure 4d. Additional images of membranes for each laser irradiation dose can be found in the Figure S1.

In order to better understand both the composition and structure of individual defects in the nanoporous membranes, we obtain atomic resolution AC-STEM images. Figure 5a shows the morphology of a typical laser-induced defect (D ~ 10^3 W/cm²), outlined in yellow (additional defects in Figure S4). EELS analysis of the bright islands visible on the irradiated membrane reveals a peak at an energy loss of 532 eV that corresponds to the oxygen K-edge (Figure 5e). This peak is only observed in the bright clustered features and not elsewhere on the membrane. The oxide is also seen to deposit irregularly inside the expanded defect, held together by an amorphous, carbon-based matrix. Closer observation of defect edges shows the clear demarcation of the intact WS₂ lattice and the amorphous carbon inside the defect, while no clear lattice structure is seen in the oxide (Figure 5c-d). We note that unlike molybdenum-based TMDs, where the absence of molybdenum oxide (MoO₃) after photo-oxidation experiments was attributed to dissolution of the oxide in water,¹⁹,²¹ previous reports on tungsten-based TMDs using X-ray photoelectron spectroscopy and scanning photoemission microscopy have indicated the appearance of tungsten oxide oxidation states after laser exposure.¹,²²,²³,⁴³ This agrees with our direct observations of oxide islands on the laser-irradiated WS₂ membranes. The amorphous carbon, which is seen to clog part of the defects, shows up in the EELS background spectrum (Figure 5e) and is likely the result of the polymer-based transfer process and/or the underlying perforated carbon film.²⁸,⁴⁴–⁴⁶ Under prolonged electron beam (AC-STEM) exposure, the carbon contamination is seen to expand until it ultimately clogs the defect entirely (Figure S3). Although the carbon contamination decreases the total nanoporous area of the membrane, it also reduces
the minimum effective hole size to the nanometer scale and gives strength to the suspended membranes, which can facilitate catalysis applications.

We classify regions of the laser-induced defects into two distinct parts: an amorphous carbon-clogged region and a nanoporous region (Figure 5a). For very large defects (Figure 5b), multiple disjointed nanopores are present due to interspersed oxide clusters held together by the amorphous carbon, thus giving a perforated appearance to a single defect (Figure S4). We quantify the dimensions of the nanopores in the suspended membranes using a thresholding function in ImageJ and obtain a distribution of the effective nanopore diameter as a function of laser irradiation dose (Figure 5f). Effective nanopore diameter is taken here to be the diameter of a single circular nanopore with the same area as the irregularly-shaped nanopore inside the defect. The smallest defect observed in our samples has an area of ~ 300 nm² while the minimum effective nanopore diameter was found to be ~ 15 nm. With increasing laser irradiation dose, an increase in both the average and maximum effective nanopore diameter is seen. Calculating the nanoporous area percentage of the exposed membranes results in a linear dependence on the laser irradiation dose given by the empirical formula:

\[
\text{Nanoporous area (\%) = } a \times D + b
\]

where \( a = 1.2 \times 10^{-4} \) cm²/W and \( b = 0.42 \) are the fitting parameters (Figure 5g).

From our observations, the photo-oxidation mechanism seems to occur in two ways: (i) formation of oxide islands via reaction of water or dissolved oxygen with the WS₂ lattice and possible replacement or dislocation of sulfur atoms,²³ and (ii) oxidation and expansion of intrinsic defects into triangular defect clusters via reaction of dissolved oxygen with the dangling bonds of the defects.²⁰,²¹ The oxide that is formed by the latter process clogs the defect held together by amorphous carbon that is present from the transfer process. If the expanded defect
becomes large enough \((i.e. > 300 \text{ nm}^2)\), the carbon-clogged region collapses and gives rise to nanopores inside the defect. It should be noted here that based on previous studies using higher laser powers the observed defects are not expected to be thermally-induced as the maximum power reaching the membrane was measured and limited to below 2 mW \((P \sim 1.44 \text{ mW})\) during our irradiation experiments.\(^{22,47,48}\)

**Conclusion**

In summary, we demonstrated the first study on the fabrication of atomically-thin WS\(_2\) membranes with tunable porosity via a photo-oxidation-induced process that avoids many of the sensitive processing conditions required of other techniques. While no laser-induced defects were seen in air, an aqueous environment produced defects for laser irradiation doses in the range \(10^2-10^5 \text{ W/cm}^2\). We found that the creation of defects leads to the relative lowering of the concentration of neutral excitons compared to trions \((n\text{-type doping})\), combined with a decrease in PL peak intensity with increase in irradiation dose due to defect-related degradation. AC-STEM images of the irradiated membranes show triangular clustered defects, which contain a combination of nanopores and tungsten oxide islands held together by an amorphous carbon matrix, which arises due to the PMMA-based sample preparation. The smallest defect size obtained was \(\sim 300 \text{ nm}^2\), while the minimum effective diameter of nanopores inside the defect was \(\sim 15 \text{ nm}\). Tunable membrane porosity was also realized through a linear dependence of nanoporous area percentage on the laser irradiation dose, with mechanical collapse of most of the membranes at doses \(\sim 10^5 \text{ W/cm}^2\). Combined with computer-controlled, time-resolved laser rastering in a desired pattern (not used in this study), these observations lay the foundation for facile and scalable fabrication of TMD nanopores and nanoporous membranes.
